In this paper, we focus on the control of the mean-field equilibrium of nonlinear networks of the Langevin type in the limit of small noise. Using iterative linear approximations, we derive a formula that prescribes a control strategy in order to displace the equilibrium state of a given system and remarkably find that the control function has a “universal” form under certain physical conditions. This result can be employed to define universal protocols useful, for example, in the optimal work extraction from a given reservoir. Generalizations and limits of application of the method are discussed.

I. INTRODUCTION

Thermodynamics of finite-size systems is a rapidly expanding field. From the theoretical side, a number of nonequilibrium relations have been established [1–5], starting with the pioneering work of Evans *et al.* [6]. In the meantime, experimental techniques were developed to probe mesoscopic systems, such as colloidal particles and macromolecules, allowing for the experimental validation of some of these nonequilibrium thermodynamic relations [5,7–10]. Present control methods are based on finding either the control function $\lambda(t)$ [11–14] or the optimal probability density function governing $\lambda(t)$ [15,16] in order to attain a certain mean or variance. Controlling rare events is another problem of relevance, addressed either by path integration methods [17–19] or by the Wentzel-Kramers-Brillouin (WKB) approximation [20,21]. An interesting application of the WKB method to reaction-diffusion systems has been developed in Refs. [22,23].

Here we focus on the problem of controlling nonlinear systems with finite degrees of freedom subject to weak noise. Our control scheme involves driving a system from one equilibrium state to another by an external protocol while minimizing some cost functional. A first step towards determining an optimal protocol in stochastic thermodynamics has been taken by Schmiedl and Seifert [24], who considered linear systems and minimized the physical work performed by the control force on the system. Here we generalize this result by obtaining expressions prescribing the control of the mean-field equilibrium of *nonlinear* networks, constrained by a *generic* cost functional. More interestingly, we find a special limiting behavior for which the optimal protocol becomes independent of the particular form on the cost functional, i.e., taking a universal form and, thus, allowing for the design of universal optimal controllers.

A general multidimensional stochastic system can be written as

$$\frac{d\mathbf{q}}{dt} = \mathbf{F}(\mathbf{q}) + \sqrt{2}\boldsymbol{\xi}(t) + \lambda(t), \quad (1)$$

where $\lambda(t)$ is a control parameter and $\boldsymbol{\xi}$ is the standard white noise, i.e., $\langle \boldsymbol{\xi}(t) \rangle = 0$, $\langle \xi_i(t)\xi_j(t') \rangle = \delta_{ij}\delta(t-t')$. We take the

noise intensity to be unity, which is always possible after rescaling t and $\mathbf{F}(\mathbf{q})$. Equation (1) is general and can be used to describe a broad class of physical, biological, and/or ecological systems.

Our goal is to transition a system initially occupying an equilibrium state \mathbf{q}_0^* to $\mathbf{q}_0^* + \mathbf{C}$ using a control function that varies from $\lambda(t=0) = \lambda_s$ to $\lambda(\tau) = \boldsymbol{\varepsilon}$ within some finite time τ . Furthermore, we would like the control to be *optimal*. This means that our protocol $\lambda(t)$ must minimize some cost functional,

$$\mathcal{W} = \int_0^\tau dt \mathcal{L}(\lambda, \dot{\lambda}, \mathbf{q}, \dot{\mathbf{q}}). \quad (2)$$

Here, we consider a general class of Lagrangians of the form

$$\mathcal{L} = \langle \Gamma(\mathbf{q}, \dot{\mathbf{q}}, \lambda, \dot{\lambda}) \rangle. \quad (3)$$

We do not assume an explicit form for $\mathbf{F}(\mathbf{q})$ and $\Gamma(\mathbf{q}, \dot{\mathbf{q}}, \lambda, \dot{\lambda})$. However, we assume that $M_{ij}(\lambda)$ is a simply connected differentiable manifold, whose real parts of eigenvalues remain negative for the range of λ to be applied. This ensures that the shift in equilibrium $\mathbf{q}^*(\lambda)$ takes place smoothly as λ is varied.

The paper is organized as follows: In Sec. II we introduce the main idea. In Sec. III we evaluate the protocol for special limits. In particular, in Sec. III we identify a special class of Lagrangians such that the control protocol is universal, i.e., *independent* of the Lagrangian parameters. In Sec. IV we generalize the formulas derived in Sec. II. In Sec. V we consider some explicit examples and discuss our limitations. Finally we present concluding remarks in Sec. VI.

II. ITERATIVE SOLUTION TO THE NONLINEAR CONTROL PROBLEM

We start our analysis with small displacements $|\mathbf{q}_0^* + \mathbf{C}|/|\mathbf{q}_0^*| \sim 1$. That is, we move in the neighborhood of the original equilibrium. This condition will be relaxed later by iterating over many such small displacements.

To simplify our notation we will shift our origin to the original equilibrium state, i.e., $\mathbf{q} \rightarrow \mathbf{q} - \mathbf{q}_0^*$. Near this point, the system can be linearized, $\dot{q}_i \approx -\sum_j M_{ij}q_j + \lambda_j(t) + \sqrt{2}\xi_j(t)$, where $M_{ij} = M_{ij}(\mathbf{0})$ is (minus) the stability matrix evaluated around the original equilibrium. Thus, for small displacements, the problem is reduced to controlling a linear system starting from $\lambda(t=0) = \mathbf{0}$ and ending at $\lambda(\tau) = \boldsymbol{\varepsilon}$ in

*gforte@nd.edu

†dvural@nd.edu

the finite time τ . Since we aim to perform a small displacement, we also can expand the Lagrangian \mathcal{L} around $\lambda, \dot{\lambda} \sim \mathbf{0}$. Thus, omitting constant terms, the expanded Lagrangian has the form

$$\mathcal{L} = \langle \mathbf{h}(\mathbf{q}, \dot{\mathbf{q}}) \cdot \lambda \rangle + \langle \mathbf{g}(\mathbf{q}, \dot{\mathbf{q}}) \cdot \dot{\lambda} \rangle. \quad (4)$$

The expansion around $\lambda, \dot{\lambda} \sim \mathbf{0}$ automatically implies an expansion around the equilibrium, and thus we can take

$$\mathbf{g} \approx \sum_{i=1}^N (\gamma^i Q_i + \eta^i \dot{Q}_i) + \text{const}, \quad (5)$$

$$\mathbf{h} \approx \sum_{i=1}^N (v^i Q_i + \alpha^i \dot{Q}_i) + \text{const}, \quad (6)$$

$$\mathcal{L} \approx \sum_{i=1}^N (v^i Q_i \lambda_i + \alpha^i \dot{Q}_i \lambda_i + \gamma^i Q_i \dot{\lambda}_i + \eta^i \dot{Q}_i \dot{\lambda}_i), \quad (7)$$

where $Q_i = \langle q_i \rangle$ is the mean trajectory and v^i , α^i , γ^i , and η^i are expansion coefficients. Equation (4) is the most general form for a Lagrangian up to the first order in $\lambda, \dot{\lambda}$ and can be used to describe any system near its equilibrium. In Sec. V C we discuss some specific examples and point out to physically relevant Lagrangians that fall under this form.

Plugging Eq. (4) in Eq. (2), obtaining λ_i and $\dot{\lambda}_i$ from the mean-field equation $\dot{Q}_i = -\sum_j M_{ij} Q_j + \lambda_i(t)$ and omitting the terms that do not enter the minimization explicitly, we obtain (for a full derivation cf. the Appendix),

$$\begin{aligned} \mathcal{W} = \sum_{i=1}^N \left\{ \gamma^i [Q_i \dot{Q}_i]_0^\tau + \frac{\eta^i}{2} [\dot{Q}_i^2]_0^\tau \right. \\ \left. + M_{ii} \int_0^\tau dt (a^i \dot{Q}_i^2 + v^i Q_i^2) \right. \\ \left. + \sum_{j \neq i} M_{ij} \int_0^\tau dt (v^i Q_i Q_j + \eta^i \dot{Q}_i \dot{Q}_j) \right\}, \quad (8) \end{aligned}$$

where

$$a^i = \eta^i + \frac{\alpha^i - \gamma^i}{M_{ii}}. \quad (9)$$

Using Euler-Lagrange equations to minimize this functional, we obtain

$$\sum_{j=1}^N (A_{ij} \ddot{Q}_j + B_{ij} Q_j) = 0, \quad (10)$$

where the matrices A_{ij} and B_{ij} are

$$A_{ij} = 2a^j \delta_{ij} - \frac{M_{ij}}{M_{jj}} \eta^j + \frac{M_{ij}}{M_{jj}} \delta_{ij} \eta^i, \quad (11)$$

$$B_{ij} = -2v^j \delta_{ij} - \frac{M_{ij}}{M_{jj}} v^j + \frac{M_{ij}}{M_{jj}} \delta_{ij} v^i. \quad (12)$$

Since the system Eq. (10) is linear and homogeneous, the general solution is of the form $Q_j^\beta = \sum_k \beta_{jk} \phi_k(t)$, where β_{jk} 's are constant coefficients and $\phi_k(t)$'s are of the form given in Eq. (20), Sec. IV, where we discuss the technical details.

Using the boundary condition $\mathbf{Q}(0) = \mathbf{0}$, the matrix elements β_{jk} can be determined by substituting Q_j^β into \mathcal{W} and

letting $\partial \mathcal{W} / \partial \beta_{jk} = 0$. The final result is a linear system of dimension N^2 , which can be solved by inverting the matrix of coefficients (see Sec. IV). Once β_{jk} is known, the optimal protocol follows from the relation:

$$\lambda_i = \sum_{j=1}^N M_{ij} Q_j^{\beta_{\text{opt}}} + \dot{Q}_i^{\beta_{\text{opt}}}. \quad (13)$$

Once the first iterative step has been performed, the new equilibrium is given by $\mathbf{q}^*(\boldsymbol{\varepsilon})$ with $\boldsymbol{\varepsilon} = \lambda(t = \tau)$. Starting from the new equilibrium, the procedure can be iterated in a new time interval, say $[\tau, 2\tau]$, as long as the largest real part of the eigenvalues of the stability matrix $M_{ij}(\boldsymbol{\varepsilon})$ is strictly negative with the new equilibrium $\mathbf{q}^*(\boldsymbol{\varepsilon})$ playing the role of the original equilibrium in the first iterative step.

III. SPECIAL CASES

For pedagogical purposes, we first evaluate the above formulas for weakly interacting systems ($M_{ii} \gg M_{ij}$, $i \neq j$). We then will generalize these results to systems for which the interactions need not be weak. $M_{ii} \gg M_{ij}$ means that self-interactions are more frequent than intraspecies ones. This assumption greatly simplifies calculations while also allowing us to introduce the essential features of our strategy, which we also use to solve the more general case where the interactions are not necessarily weak.

When $M_{ii} \gg M_{ij}$ for all $i \neq j$'s, Eq. (10) simplifies to

$$a^i \ddot{Q}_i - v^i Q_i = 0. \quad (14)$$

A real solution of Eq. (14) can be obtained only when $v^i/a^i > 0$ and is given by

$$Q_i^\beta(t) = 2\beta_i \sinh(r_i t), \quad (15)$$

where $Q_i^\beta(0) = 0$, $r_i = \sqrt{v^i/a^i}$ and β_i is a constant, whose optimal value is to be determined by differentiating

$$\begin{aligned} \mathcal{W} = \sum_{i=1}^N \left\{ \gamma^i [Q_i \dot{Q}_i]_0^\tau + \frac{\eta^i}{2} [\dot{Q}_i^2]_0^\tau \right. \\ \left. + M_{ii} \int_0^\tau dt (a^i \dot{Q}_i^2 + v^i Q_i^2) \right\}, \quad (16) \end{aligned}$$

with respect to β_i and setting it to zero.

Next, using the relations $\lambda_i = \dot{Q}_i + \sum_j M_{ij} Q_{ij}$, $\dot{\lambda}_i = \ddot{Q}_i + \sum_j M_{ij} \dot{Q}_{ij}$, and Eq. (15), the single terms in Eq. (16) take on the form

$$\begin{aligned} \gamma^i [Q_i \dot{Q}_i]_0^\tau &= \gamma^i \{ Q_i^*(\varepsilon_i) [-2M_{ii} \beta_i \sinh(r_i \tau) \\ &\quad + \varepsilon_i] \}, \\ \frac{\eta^i}{2} [\dot{Q}_i^2]_0^\tau &= \frac{\eta^i}{2} \{ [-2M_{ii} \beta_i \sinh(r_i \tau) + \varepsilon_i]^2 \}, \end{aligned}$$

$$M_{ii} \int_0^\tau dt (a^i \dot{Q}_i^2 + v^i Q_i^2) = 2M_{ii} \beta_i^2 a^i r_i \sinh(2r_i \tau).$$

We now set $\partial\mathcal{W}/\partial\beta_i = 0$ to obtain the optimal value $\beta_i = \beta_i^{\text{opt}}$, given by

$$\beta_i^{\text{opt}} = \frac{\varepsilon_i + \frac{\gamma^i}{\eta^i} q_i^*(\varepsilon_i)}{4\frac{a^i}{\eta^i} r_i \cosh(r_i \tau) + 2M_{ii} \sinh(r_i \tau)}.$$

From the above solution we can derive the optimal protocol explicitly

$$\begin{aligned} \lambda_i^{\text{opt}}(t) &= \dot{Q}_i^{\beta_{\text{opt}}}(t) + M_{ii} Q_i^{\beta_{\text{opt}}}(t) \\ &= \frac{r_i + M_{ii} \tanh(r_i t)}{2\frac{a^i}{\eta^i} r_i + M_{ii} \tanh(r_i \tau)} \left(\varepsilon_i + \frac{\gamma^i}{\eta^i} q_i^*(\varepsilon_i) \right). \end{aligned} \quad (17)$$

This formula defines the most general protocol to induce an optimal infinitesimal displacement for a system characterized by either a single degree of freedom or weakly interacting systems. It works for any nonlinear system, provided that the iterative procedure can be applied and for the general class of cost functionals given in Eq. (7).

A. Design of universal controllers

The general solution (17) reveals an interesting class of Lagrangians for which the optimal control protocol becomes independent of the parameters defining the cost functional. Specifically, if \mathcal{L} is such that $\alpha^i = \gamma^i = 0$, Eq. (9) gives $a^i/\eta^i = 1$ in Eq. (17), and when $r_i \tau \ll 1$, Eq. (17) loses all constants associated with the Lagrangian, and we get a universal protocol,

$$\lambda_i^{\text{opt}}(t) \approx \frac{\varepsilon_i(1 + M_{ii}t)}{(2 + M_{ii}\tau)}. \quad (18)$$

Note that the condition $r_i \tau \ll 1$ giving rise to the universal protocol can always be satisfied by choosing a sufficiently small τ . Picking a sufficiently small τ is also important to avoid noise-driven transitions to other equilibria. Ideally, τ must be smaller than the fastest of such transitions.

Although (18) has been derived by Schmiedl and Seifert [24] assuming a linear system subject to the minimization of the work functional, here we identify this formula as a special case of a more general result, i.e., our (17). We also identify (18) as a universal control strategy that works beyond linear systems and specific work or cost functionals, provided that the Lagrangian belongs to the particular class identified by (5) and (6) with $\alpha^i = \gamma^i = 0$. In Sec. V C we will discuss some specific examples of Lagrangians belonging to such a universal class.

Once the system has been brought to the new equilibrium point $q_i^*(\varepsilon_i)$, this point can now be considered as the new original equilibrium, and the procedure can be repeated again, provided that all the parameters are updated by expanding, this time, around $q_i^*(\varepsilon_i)$. For example, Fig. 1 (main panel) shows the iteration of the map in Eq. (18) for a quadratic system, i.e., the universal behavior, from $\lambda = 0$ to $\lambda = \lambda_{\text{max}} = K\varepsilon$ ($K = 5$), each segment evaluated in a time interval of the form $[(n-1)\tau, n\tau]$ ($n = 1, \dots, K$). The slope of every segment depends on $M_{ii}[(n-1)\varepsilon_i]$, which must be evaluated along the function $q_i^*(\lambda)$.

The control function Eq. (17) in the nonuniversal regime is shown in Fig. 1 (inset) for a single iteration starting from

FIG. 1. (Main panel) The iteration of the universal formula in Eq. (18) with the local slopes $M_{ii}(\lambda)$ evaluated along the stable branch of a simple quadratic system defined by $F(q) = \mu q - Aq^2$ ($\mu = 2$, $A = 1$) [cf. see also Fig. 2(a)]. The iterations start at the original equilibrium μ/A and bring the system to the point $\mu/A + \mu/2A$, changing the protocol by a quantity $\varepsilon = 10^{-1}\mu/A$ at each iteration; (inset) Eq. (17) referred to a single iteration. Here we show the nonuniversal behavior for $\gamma^i = \alpha^i = 0$. The iteration in this case cannot be drawn without knowing all the details of the Lagrangian, i.e., the constants r_i at any iterative step. The plot refers to the special case with $r_i = M_{ii} = 1$ in the first iterative step.

the natural equilibrium. More iterations of the formula are not shown since we would need all the details of the cost functional. For this case, we took $\gamma^i = \alpha^i = 0$ and $r_i = M_{ii} = 1$.

In passing, we note that Eqs. (18) and (17) are characterized by discontinuities at end points, i.e., at $t \rightarrow 0^-$ and $t \rightarrow \tau^+$. We recall that such discontinuities commonly appear in solutions of optimal control problems [24–26].

IV. GENERAL CASE

When $M_{ii} \gg M_{ij}$ does not hold, the general solution for the second order system in Eq. (10) can be written as

$$Q_j = \sum_k [\beta_{jk} \exp(i\sqrt{\omega_k}t) + \beta'_{jk} \exp(-i\sqrt{\omega_k}t)] + \text{c.c.},$$

where c.c. indicates the complex conjugate of the first term (\mathbf{Q} must be real) and ω_k^{-1} is the (in general, complex) eigenvalues of the matrix $\hat{B}^{-1}\hat{A}$ [see Eqs. (11) and (12) for the definition of matrices \hat{B} and \hat{A}]. The condition $\mathbf{Q}(\mathbf{0}) = \mathbf{0}$ requires $\beta_{jk} = -\beta'_{jk}$, and thus, we can write the final solution in a real form as

$$Q_j = \sum_k \beta_{jk} \phi_k(t), \quad (19)$$

$$\phi_k(t) = 2 \sinh(\omega_k^{\text{(Re)}} t) \cos(\omega_k^{\text{(Im)}} t), \quad (20)$$

with $i\sqrt{\omega_k} = \omega_k^{\text{(Re)}} + i\omega_k^{\text{(Im)}}$ ($i^2 = -1$) and $\beta_{jk} \in \mathbb{R}$.

The next step is the minimization of the cost functional in Eq. (8). Using Eq. (19) and remembering that, around the

equilibrium, we have

$$\dot{Q}_i = \sum_j M_{ij} Q_j + \lambda_i(t) = \sum_{jk} M_{ij} \beta_{jk} \phi_k + \lambda_i(t),$$

the minimization of (8) is performed by setting $\partial \mathcal{W} / \partial \beta_{pp'} = 0$. The calculation is straightforward, however, tedious. Here, we report the final result,

$$\sum_i \left\{ -[\gamma^i Q_i^*(\tau) + \eta^i \varepsilon_i] M_{ip} \phi_{p'}(\tau) + \sum_{jk} (M_{ij} \{ \eta^i M_{ip} \phi_k \phi_{p'} + \delta_{ip} [\tilde{\Gamma}_{kp'}^i + \tilde{\Gamma}_{kp'}^j + \delta_{ij} (\Gamma_{kp'}^i - \tilde{\Gamma}_{kp'}^i) + \delta_{ij} (\Gamma_{kp'}^j - \tilde{\Gamma}_{kp'}^j)] \}) \beta_{jk} \right\} = 0, \quad (21)$$

where $\Gamma_{kk'}^i$ and $\tilde{\Gamma}_{kk'}^i$ are defined as

$$\Gamma_{kk'}^i = a^i \int_0^\tau dt \dot{\phi}_k \dot{\phi}_{k'} + v^i \int_0^\tau dt \phi_k \phi_{k'}, \quad (22)$$

$$\tilde{\Gamma}_{kk'}^i = \eta^i \int_0^\tau dt \dot{\phi}_k \dot{\phi}_{k'} + v^i \int_0^\tau dt \phi_k \phi_{k'}. \quad (23)$$

Equation (21) is a linear system of equations with unknowns β_{jk} . Summing over i and relabeling the indices such that $jk \rightarrow q' = 1, 2, \dots, N^2$ and $pp' \rightarrow q = 1, 2, \dots, N^2$, the linear system becomes

$$C_q + \sum_{q'} T_{qq'} \beta_{q'} = 0,$$

where C_q and $T_{qq'}$ consist of known constants, given with the problem. The solution of the above system can be found if and only if $\det(T_{qq'}) \neq 0$ and can be written as

$$\boldsymbol{\beta} = \boldsymbol{\beta}_{\text{opt}} = -\hat{T}^{-1} \mathbf{C}, \quad (24)$$

Once the optimal $\boldsymbol{\beta}$ value is known, the protocol follows from Eq. (13) and (19), evaluated for $\boldsymbol{\beta} = \boldsymbol{\beta}_{\text{opt}}$.

Just as in Eq. (18), when $\gamma^i = \alpha^i = 0$ (i.e., $\tilde{\Gamma}_{kk'}^i = \Gamma_{kk'}^i$), it is possible to find an explicit expression for the protocol in the limit of $\tau \rightarrow 0$. In this case we explicitly get

$$\lambda(t) = (t \hat{M} + \hat{I})(\hat{I} + \tau \hat{\mathcal{G}}^{-1} \hat{M})^{-1} \hat{\mathcal{G}}^{-1} \boldsymbol{\varepsilon}, \quad (25)$$

where matrix $\hat{\mathcal{G}}$ is given by

$$\mathcal{G}_{ij} = \frac{M_{ij}}{M_{ii}} \left(1 + \frac{\eta^j}{\eta^i} \right).$$

As we see, contrary to the weakly interacting case we do not necessarily obtain a universal protocol since the control function now depends on the ratio of the η 's (but not on the eigenvalues ω_k). Nevertheless, a ‘‘milder’’ universality is recovered when the η 's are similar to one other,

$$\left| \frac{\eta^j}{\eta^i} \right| \sim O(1).$$

This condition should not be viewed as an unlikely conspiracy of parameters. In a typical thermodynamic system, all particles will have the same physical properties, and any cost functional that treats all particles on equal footing (e.g., physical work) will fit the bill. In such cases the control function will be

universal in the sense that it will not depend on *what* the physical properties of the particles are as long as the physical properties of all particles are the same $\eta^i = \eta$.

V. EXAMPLES AND LIMITS OF APPLICATION

We will now establish the domain of applicability of our framework and discuss its limitations. We will do so by picking a number of specific examples of dynamic systems and cost functionals and illustrate the workings or limitations of our formulas.

We will start with two one-dimensional systems: the logistic model and a periodic potential model. We will then move on to a multispecies generalization of a Lotka-Volterra ecological model. Finally, we will discuss a number of specific cost functionals, motivated by mechanical and thermodynamic applications.

A. One-dimensional systems

An important limitation of our framework is that $q^*(\lambda)$ must exist, remain stable for the range of λ in question, and be a continuous function. Furthermore, if the system has multiple stable points or if the stable path $q^*(\lambda)$ bifurcates, then noise can trigger undesirable transitions to other equilibria.

To exemplify these limitations, we discuss a specific system which has multiple stable points, one of which, assumed to be absorbing $F(q) = \mu q - Aq^2$, $\mu/A > 0$. Suppose we originally start from the stable point $q_0^* = \mu/A$. As we add in the control λ , both stable points shift [Fig. 2(a) main panel]. As long as rare events are ignored, our procedure can move the system to any arbitrary state $q > q_0^*/2$; however, it is essential that, as we move along the upper branch $q^*(\lambda)$, noise does not transition the system to the lower (absorbing) branch.

With rare events, the success of our protocol depends on the choice of τ and can be evaluated. We simulate many trajectories moving from μ/A to $\mu/A + \delta(\mu/A)$ (where $\delta \ll 1$) within a time τ and count the fraction of trajectories that crash to the lower branch. The result is shown in Fig. 2(a) the inset. As we see, for $\tau \ll 1$, probability of success approaches 1. Furthermore, and regardless of τ , as we iterate along $q^*(\lambda)$ the likelihood of success keeps increasing since the further we move away from the absorbing state, the more the expected crash time increases [cf. Fig. 2(b)].

We point out that whenever $\alpha^i = \gamma^i = 0$, having a high success rate is equivalent to the applicability of the universal controller. This is because success and universality both hinge on $r\tau \ll 1$.

Of course, we cannot control rare events using the iterative technique developed here because in the long time, a rare jump will always occur, bringing the system to the absorbing boundary (if there is one). More refined techniques, based on the evaluation of the large deviation function [27] should be applied to control rare events. These techniques are based on a path integral description of the stochastic dynamics [17] and/or the evaluation of the main contribution to the path integral (the WKB method) [20,21,28,29].

The technique discussed in this paper works perfectly in the deterministic limit. In the case of stochastic systems, the best we can do is to choose a τ that maximizes the success rate in

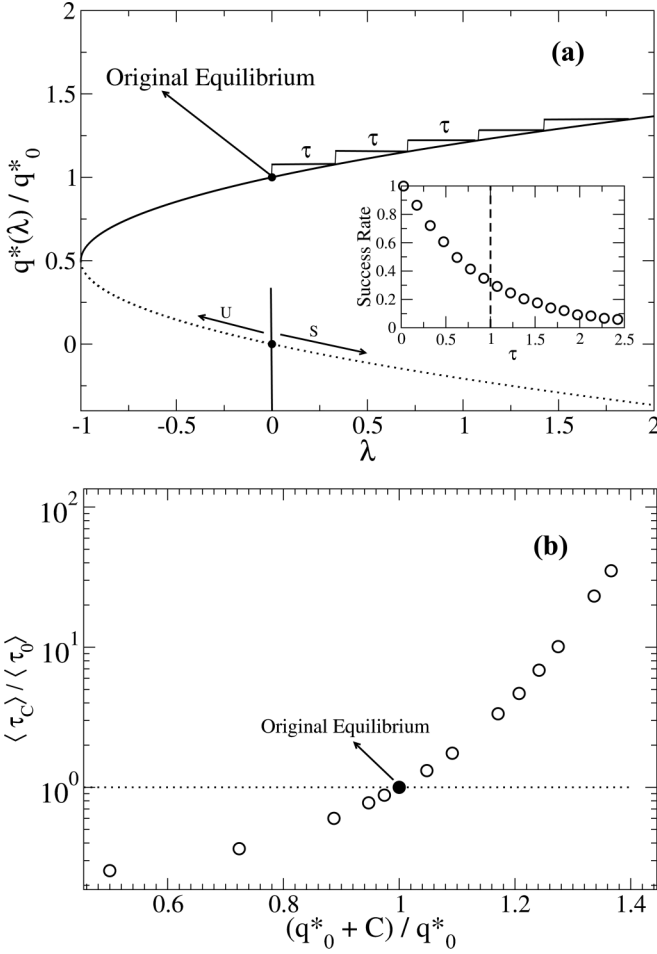

FIG. 2. (a) Main panel: the function $q^*(\lambda)$ for the quadratic system defined by $F(q) = \mu q - Aq^2$ ($\mu = 2$, $A = 1$). After applying the control protocol in a finite time τ , the system sets on the new equilibrium point $q^*(\lambda)$. From here, we can linearize again and iterate the single step procedure; the bottom branch is both unstable (U) and stable (S). (a) The inset: the success rate of the control strategy, i.e., the number of trajectories which reach the absorbing boundary while applying the first iteration from the natural equilibrium to a new equilibrium point infinitesimally close to it; (b) a final equilibrium value $q^*_0 + C$ and an average extinction time $\langle \tau_C \rangle$ correspond to any iteration, which, once compared with $\langle \tau_0 \rangle$, show results highly improved, even for small displacements from the natural equilibrium.

a given time window. Now, we investigate another multistable system that has a periodic potential $F(q) = \sin(2\pi q) = -\partial_q U(q)$ with $U(q) = \cos(2\pi q)/2\pi$. We assume that the system starts from $q^*_0 = 1/2$ [Fig. 3 (the inset)]. In the limiting case of vanishing noise, we can safely iterate the control procedure along the geometric locus defined by $q^*(\lambda)$ as shown in Fig. 3 (main panel). However we see that the technique fails at $|\lambda| \geq 1$, even for deterministic systems since there comes a point where the system loses all stable points and we cannot proceed further with our method. For such cases, a nonequilibrium procedure is in order. When we cannot neglect the influence of the noise, we should take into account that the jumps between stable equilibria occur at a rate of $\sim \exp[U(q = 1)]$ [30]. Thus, increasing λ has the effect of increasing the transition frequency by a factor of $\exp(\lambda)$. If our

FIG. 3. (Main panel) The function $q^*(\lambda)$ for the multistable system defined by $F(q) = \sin(2\pi q)$. Starting from the original equilibrium $q^*_0 = 1/2$ we can again apply the iterative procedure moving along the line $q^*(\lambda)$. However, we immediately realize that for $\lambda \geq 1$ the system is always out of equilibrium and the proposed technique fails; (the inset) the function $F(q) = \sin(2\pi q) + \lambda$ for different values of λ .

goal is to trigger a jump to another state, we safely can employ the optimal procedure until we reach a value of λ that gives us the desired jumping rate. This procedure can also be used to inhibit the jumps between two stable equilibria. In this case, rather than moving λ from 0 to $\lambda_f < 1$, we must move λ from 0 to $\lambda_f > -1$, which would inhibit the jumping frequency by a factor of $\exp(-|\lambda_f|)$. In both cases, we can ensure a high success rate while iterating the protocol by picking up a suitable τ as discussed before.

B. The Lotka-Volterra model

In this section we discuss a successful application of our procedure to the multispecies generalization of the Lotka-Volterra model defined by

$$\frac{dq_i}{dt} = \mu_i q_i + \sum_{j=1}^N J_{ij} q_j q_i + \lambda_i(t), \quad i = 1, \dots, N. \quad (26)$$

Here N is the number of species, μ_i is the intrinsic growth rate of species i , and J_{ij} quantifies the interactions between species i and j . Equation (26) has a single internal fixed point \mathbf{q}^*_0 for $\lambda = \mathbf{0}$, given by

$$\mathbf{q}^*_0 = -\hat{J}^{-1} \boldsymbol{\mu}. \quad (27)$$

Here we will evaluate our formulas for a competitive model ($J_{ij} \propto -J_{ji}$ and $J_{ii} < 0$) with $N = 10$ species. In this case, the equilibrium point in Eq. (27) is globally stable [31]. We draw the parameters J_{ij} from a Gaussian distribution with zero mean and unit variance and choose the original equilibrium point \mathbf{q}^*_0 at random such that $q^*_{0,i}$ is distributed uniformly between 0 and 1. The parameters μ_i are fixed by inverting the relation in Eq. (27).

The starting point of our technique is the displacement of the system from the original equilibrium to a new one $\mathbf{q}^*(\lambda)$, thanks to the application of an external controller λ such that

FIG. 4. (Main panel) Success rate of the ten-dimensional Lotka-Volterra system; (the inset) the largest real part of the stability matrix as a function of λ .

$\lambda(0) = \mathbf{0}$ and $\lambda(\tau) = \boldsymbol{\varepsilon}$ with $|\boldsymbol{\varepsilon}| \ll 1$. Thus, we first need to solve the equation,

$$\mu_i q_i + \sum_{j=1}^N J_{ij} q_j q_i + \lambda_i = 0,$$

and check if the largest real part of the stability matrix $\hat{M}(\lambda)$, evaluated at $\mathbf{q}^*(\lambda)$, is strictly negative. If so, we can safely apply our iterative technique to this nonlinear and multidimensional problem. In Fig. 4 (the inset) we show the largest real part of $\hat{M}(\lambda)$ evaluated numerically as a function of the magnitude $\lambda = |\lambda|$ when $\lambda = \lambda(1, 1, 1, \dots, 1)$.

In particular $\lambda = K\varepsilon$ with $\varepsilon \ll 1$ and K as the iterative step.

As we performed in the single-species case, we evaluate the success rate of our technique for this multidimensional system. Indeed, as long as we move along the line in Fig. 4 (the inset) we can safely employ our technique in the deterministic case. However, when the noise is loud enough to destabilize the globally stable point $\mathbf{q}^*(\lambda)$ we must be cautious about the success rate of our method. In particular, using Eq. (25), we displace the Lotka-Volterra system from \mathbf{q}_0^* to a nearby point $\mathbf{q}^*(\lambda_f)$ with $\lambda_f = \varepsilon(1, 1, 1, \dots, 1)$ and $\varepsilon = 10^{-3}$. We repeat the process $N_e = 1000$ times in a fixed time-interval $[0, \tau]$ and count how many of the N_e total realizations are such that at least one of the ten species in the Lotka-Volterra system goes extinct. The success rate is shown in the main panel of Fig. 4 and, as in the single-species case, approaches one as $\tau \rightarrow 0$, which justifies the limit in Eq. (25).

C. Explicit examples of cost functionals

The physical interpretation of the universal class of Lagrangians can be understood better with a few explicit examples. Following Ref. [24], we consider a mechanical system evolving according to the equation,

$$\frac{dq}{dt} = -\frac{\partial V(q, \lambda)}{\partial q} + \sqrt{2}\xi,$$

where

$$V(q, \lambda) = \frac{1}{2}(q + \lambda)^2.$$

We thus have (averaging over the noise) $\dot{q} = -q + \lambda$. The work \mathcal{W} performed by λ on the system is as follows:

$$\mathcal{W} = \int_0^\tau dt \dot{\lambda} \left\langle \frac{\partial V}{\partial \lambda} \right\rangle = \int_0^\tau dt \dot{\lambda} q, \quad (28)$$

giving a Lagrangian of the form (7) with $\eta = 1$ and all the other parameters equal to zero. The Lagrangian in this case is not approximate and belongs to the universal class. We explicitly observe that in Eq. (17) $r^i = \sqrt{v^i/a^i}$ goes to zero as $\sim \sqrt{v^i}$ when all the parameters in Eq. (7) are zero with the exception of η . Thus, in order to get the universal behavior, we do not even need to take the limit $\tau \rightarrow 0$. It will be enough to take the limit for $v^i \rightarrow 0$, which again gives Eq. (18). The same conclusion holds more generally, for the potential,

$$V(\mathbf{q}, \lambda) = \frac{1}{2}(\mathbf{q} - \lambda) \cdot (\mathbf{q} - \lambda) \Rightarrow \mathcal{L} = \dot{\mathbf{q}} \cdot \dot{\lambda}. \quad (29)$$

Another example of a Lagrangian belonging to the universal class is

$$\mathcal{L} = \frac{1}{2}(\dot{q} - \dot{\lambda})^2. \quad (30)$$

In a mechanical framework, this might be interpreted as a minimization of the effect of frictionlike forces between the system and the controlling agent.

The linearized form [Eq. (7)] of the above Lagrangian is

$$\mathcal{L} \approx -\dot{q}\dot{\lambda} + \dots,$$

which belongs to the universal class with $\eta^i = -1$. The universal limit follows from Eq. (17) taking $v^i \rightarrow 0$, and it is valid for any τ . More generally, we can consider a Lagrangian of the form

$$\mathcal{L} = \frac{1}{2}(q - \lambda)^2 + \frac{1}{2}(\dot{q} - \dot{\lambda})^2 \approx -q\lambda - \dot{q}\dot{\lambda} + \dots,$$

which also falls in the universal class with $v^i = \eta^i = -1$. In this case and for Eq. (30) the universal limit follows only if we pick up a sufficiently small τ such that $r^i \tau \ll 1$. A multidimensional generalization of the above Lagrangian and Eq. (30) easily is found to belong to the universal class when $\eta^i = -1$ for all i 's.

An example of a Lagrangian which does not belong to the universal class can be borrowed from the experiments with feedback traps. Such experiments often are employed to investigate the role of information in the energy exchange between physical systems [32]. If we allow for the control of the tilt in a double-well potential, we have

$$V(q, \lambda) = -\frac{1}{2}q^2 + \frac{1}{4}q^4 - \lambda(t)q,$$

i.e.,

$$\dot{q} = q - q^3 + \lambda(t) + \text{noise},$$

and the Lagrangian is given by

$$\mathcal{L} = \dot{\lambda} \langle \partial_\lambda V \rangle = -q\dot{\lambda},$$

which is of the form in Eq. (7) with all the parameters zero with the exception of γ^i . We observe that in this case a divergence appears in Eq. (17) since $\eta^i \rightarrow 0$ and our method cannot be applied. However, for general Lagrangians, such a divergence

is removed if we consider higher order terms in Eq. (7). For example, in the case of systems with $M_{ij} \ll M_{ii}$, if a nonlinear term of the form

$$\sum_i \tilde{\eta}^i \lambda_i \dot{\lambda}_i$$

is added to the Lagrangian in Eq. (7), the divergence is removed. In the presence of this addition, Eq. (17) still holds true as long as we replace

$$\begin{aligned} \eta^i &\rightarrow \eta^i + \tilde{\eta}^i, \\ \gamma^i &\rightarrow \gamma^i + M_{ii} \tilde{\eta}^i. \end{aligned}$$

However, obtaining the effect of other possible nonlinear additions is extremely challenging. Furthermore, when $M_{ij} \ll M_{ii}$ does not hold, we cannot simply get away with a trivial shift in parameters. We leave a closer investigation of nonlinear Lagrangians and their removal of singularities to a future study.

VI. CONCLUSIONS

In this paper we developed an iterative control strategy to optimally solve a certain class of nonlinear problems. The procedure is based on successive linearizations around a moving equilibrium $\mathbf{q}^*(\lambda)$ of the system plus a controller as we push the system with a control function λ . We observed that, for deterministic systems, the procedure can be implemented as long as the largest real part of the eigenvalues of the stability matrix $M_{ij}(\lambda)$ remains strictly negative. When such a condition does not hold, the procedure fails.

We have determined the effects of noise in our control framework in terms of success rate. In particular, the control time window τ must be picked as small as possible to guarantee high success. However, for large strengths of the noise, τ would become unreasonably small. Thus, our procedure can safely be applied in the limit of weak noise.

Surprisingly, we found that under certain conditions, it is possible to design universal controllers, thus engineering the control protocol without minding the particular form of the cost functional.

In closing, we should note that the additive control scheme we proposed here is not the only possible form of control. For example, a protocol of the form $\mu_i F_i(q_1, \dots, q_N)$ could be considered for a multiplicative control function μ_i . However, such a multiplicative control function cannot displace the equilibrium point. A combination of additive and multiplicative controls $\mu_i F_i(q_1, \dots, q_N) + \lambda_i$ on the other hand, may lead to nontrivial results and lead to an interesting generalization of our paper.

APPENDIX: DERIVATION OF EQ. (8)

The Lagrangian expanded around the original equilibrium \mathbf{q}_0^* is

$$\mathcal{L} \approx \text{const} + \sum_{i=1}^N (v^i Q_i \lambda_i + \alpha^i \dot{Q}_i \lambda_i + \gamma^i Q_i \dot{\lambda}_i + \eta^i \dot{Q}_i \dot{\lambda}_i).$$

From the mean-field equation,

$$\frac{dQ_i}{dt} = - \sum_j M_{ij} Q_j + \lambda_i,$$

it is possible to derive the expression of the protocol,

$$\lambda_i = \dot{Q}_i + \sum_j M_{ij} Q_j, \quad (\text{A1})$$

$$\dot{\lambda}_i = \ddot{Q}_i + \sum_j M_{ij} \dot{Q}_j. \quad (\text{A2})$$

We can thus write the Lagrangian as

$$\mathcal{L} \approx \text{const} + \mathcal{L}_1 + \mathcal{L}_2 + \mathcal{L}_3 + \mathcal{L}_4,$$

where

$$\mathcal{L}_1 = \sum_{i=1}^N v^i Q_i \left(\dot{Q}_i + \sum_j M_{ij} Q_j \right),$$

$$\mathcal{L}_2 = \sum_{i=1}^N \alpha^i \dot{Q}_i \left(\dot{Q}_i + \sum_j M_{ij} Q_j \right),$$

$$\mathcal{L}_3 = \sum_{i=1}^N \gamma^i Q_i \left(\ddot{Q}_i + \sum_j M_{ij} \dot{Q}_j \right),$$

$$\mathcal{L}_4 = \sum_{i=1}^N \eta^i \dot{Q}_i \left(\ddot{Q}_i + \sum_j M_{ij} \dot{Q}_j \right).$$

Next, we evaluate the integrals $\int_0^\tau dt \mathcal{L}_k$ for $k = 1-4$,

$$\begin{aligned} \int_0^\tau dt \mathcal{L}_1 &= \sum_i \left\{ \frac{v^i}{2} [Q_i^2]_0^\tau + M_{ii} \int_0^\tau dt (v^i Q_i^2) \right. \\ &\quad \left. + \sum_{j \neq i} M_{ij} \int_0^\tau dt (v^i Q_i Q_j) \right\} \\ \int_0^\tau dt \mathcal{L}_2 &= \sum_i \left\{ M_{ii} \int_0^\tau dt (\alpha^i \dot{Q}_i^2) \right. \\ &\quad \left. + \sum_{j \neq i} M_{ij} \int_0^\tau dt (\alpha^i \dot{Q}_i Q_j) \right\}. \end{aligned}$$

If $\mathbf{F}(\mathbf{q}) = -\nabla V(\mathbf{q})$ for some scalar function $V(\mathbf{q})$, M_{ij} (the stability matrix) is always symmetric, and the second integrals in the last expression can be evaluated

explicitly

$$\sum_{j \neq i} M_{ij} \int_0^\tau dt (\alpha^i \dot{Q}_i Q_j) = \alpha^i \left[\frac{1}{2} \sum_{j \neq i} M_{ij} Q_i Q_j \right]_0^\tau.$$

When M_{ij} has no particular symmetry, we can always decompose it in a symmetric $M_{ij}^S = (M_{ij} + M_{ji})/2$ and antisymmetric part, i.e., $M_{ij}^A = (M_{ij} - M_{ji})/2$. The antisymmetric part sums up to zero, and the above integral becomes

$$\left[\frac{\alpha^i}{4} \sum_{j \neq i} M_{ij}^S Q_i Q_j \right]_0^\tau.$$

In any case, both expressions are constants that only depend on the values of Q_i at the boundary points. Thus, they play no

role in the minimization of \mathcal{W} . Next,

$$\int_0^\tau dt \mathcal{L}_3 = \sum_i \left\{ \gamma^i [Q_i \dot{Q}_i]_0^\tau - M_{ii} \int_0^\tau dt \left(\frac{\gamma^i}{M_{ii}} \dot{Q}_i^2 \right) + \dots \right\},$$

where the \dots denote constant terms similar to the one discussed above. Finally,

$$\int_0^\tau dt \mathcal{L}_4 = \sum_i \left\{ \frac{\eta^i}{2} [\dot{Q}_i^2]_0^\tau + M_{ii} \int_0^\tau dt \left(\frac{\eta^i}{M_{ii}} \dot{Q}_i^2 \right) + \sum_{j \neq i} M_{ij} \int_0^\tau dt (\eta^j \dot{Q}_i \dot{Q}_j) \right\}.$$

Putting all the results together and omitting all the constant terms that do not influence the minimization of the Lagrangian, we get Eq. (8).
