HIGHLIGHTS

● 4 distinct events of nocturnal surface ozone (NSO) enhancement were analyzed.
● WRF model was used to simulate the atmospheric conditions during NSO enhancement.
● Results show that different atmospheric mechanisms are responsible for each event.

ABSTRACT

Four distinct nocturnal surface ozone (NSO) enhancement events were observed, with NSO concentration exceeding 80 μg/m³, at multiple ozone (O₃) monitoring stations (32 sites) in January, November and December between year 2000–2010, in Portugal. The reasonable explanation for the observed bimodal pattern of surface ozone with enhanced NSO concentration during nighttime has to be transport processes, as the surface ozone production ceases at nighttime. Simultaneous measurements of O₃ at multiple stations during the study period in Portugal suggest that horizontal advection alone cannot explain the observed NSO enhancement. Thus, detailed analysis of the atmospheric conditions, simulated with the Weather Research and Forecasting (WRF) model, were performed to evaluate the atmospheric mechanisms responsible for NSO enhancement in the region. Simulations revealed that each event occurred as a result of one or the combination of different atmospheric processes such as, passage of a cold front followed by a subsidence zone; passage of a moving surface trough, with associated strong horizontal wind speed and vertical shear; combination of vertical and horizontal transport at the synoptic scale; formation of a low level jet with associated vertical mixing below the jet stream. The study confirmed that large-scale flow pattern resulting in enhanced vertical mixing in the nocturnal boundary layer, plays a key role in the NSO enhancement events, which frequently occur over Portugal during winter months.

1. Introduction

Surface ozone (O₃) is a photo-chemically produced, highly reactive, secondary air pollutant and an important greenhouse gas (West and Fiore, 2005). Under clear sky conditions O₃ exhibits marked diurnal variability, particularly at urban and suburban areas and less prominent at rural areas. O₃ concentration starts increasing after sunrise, due to initialization of photochemical production involving nitrogen oxides (NO and NO₂) and volatile organic compounds (VOCs), and reaches the maximum concentration during early afternoon. O₃ concentration sharply decreases during late afternoon, while at night, due to surface deposition and
chemical destruction, minimum values of O₃ concentration are measured (Zhang et al., 2004). In the presence of stable nocturnal boundary layer (NBL), O₃ generally has a positive gradient from the surface to the top of the NBL (Geyer and Stutz, 2004; Stutz et al., 2004) due to insufficient downward mixing because of the nocturnal capping (Kuang et al., 2011). The aforementioned pattern of O₃ diurnal variation is observed almost routinely, although occasional enhancement of nocturnal surface ozone (NSO) is reported at various sites by many researchers (Coulter, 1990; Corrêa et al., 1997; Jain et al., 2005; Hu et al., 2012; Kulkarni et al., 2013, 2015; Klein et al., 2014). As photochemical production of O₃ ceases at nighttime and in the absence of any known sources of O₃ in the environment, due to the temporal and spatial evolution of the NSO enhancement, researchers on the mechanisms that lead to the NSO enhancement. Due to aforementioned reasons, there is still no consensus among researchers on the mechanisms that lead to the NSO enhancement. Further, the study of NSO enhancements remains a challenge, since its occurrence cannot be predicted accurately and thus, it is difficult to plan an extensive field experiment due to financial constraints among others.

The adverse effects of high daytime O₃ concentration on flora and fauna and on human health are well established (Menezes and Shively, 2001; Anenberg et al., 2009). High NSO concentration, occurring during NSO enhancement events (exceeding 80 μg/m³, which is more than O₃ exposure index AOT40 (2008/50/CE Directive)), has harmful effects on vegetation and plants, particularly in C3 and C4 plant species (Segschneider et al., 1995; Musselman and Massman, 1999; Musselman and Minnick, 2000; Takahashi et al., 2005), causing water loss and reduced whole-plant production (Matyssek et al., 1995). However, the adverse effects of high NSO concentration, during NSO enhancement events, on the human health are still not studied, as on one hand NSO is well below ppb (120 μg/ m³) threshold set by European Directives EU60 and, on the other hand, during nighttime, particularly in winter, the outdoor human activities are normally diminished eventually nonexistent. The NSO enhancement is basically the spatial redistribution of ozone by vertical mixing from lower free troposphere or within the nocturnal boundary layer, which may be important since it may affect the photochemistry of the following day therefore the overall air quality (Ravishankara, 2009). Furthermore, enhanced NSO can result in increased absorption of the outgoing longwave radiation causing localized warming due to greenhouse effect (West and Fiore, 2005; Kulkarni et al., 2015).

The general opinion about NSO enhancement is that it is highly variable in time and space (Löffler-Mang et al., 1997) and considered as an isolated or a special event. However, Sousa et al. (2011) analyzed hourly O₃ data for the period 2005–2007 from 4 stations in Portugal and found it to be more frequent. They further concluded that there was a close relationship between wind direction and the observed NSO enhancement. Similarly, Kulkarni et al. (2013) analyzed long term (2000–2010) hourly O₃ data and reported that (i) NSO concentration exceeded 40 μg/m³, 60 μg/m³ and 80 μg/m³ on more than 50%, 20% and 2% of the days respectively, during the study period, and (ii) observed an increasing trend in the NSO concentration over Portugal. The studies by Sousa et al. (2011) and Kulkarni et al. (2013) have performed statistical analysis, but lack to identify and perform in-depth analysis to determine the specific reasons for the NSO enhancement.

The aim of this study is to perform in-depth analysis of four NSO enhancement events and investigate the role of different atmospheric mechanisms responsible for repetitive occurrence of these events of varying periods and intensities with concentration exceeding 80 μg/m³, over Portugal, using both observational data and modeled simulations. The Weather Research and Forecasting (WRF) regional climate model (V3.7.1) (Skamarock et al., 2008) was used to study the influence of atmospheric conditions, and inferred possible ozone transport mechanisms due to vertical mixing from residual layer or from the free troposphere to the surface (Jaffe, 2011) during NSO enhancement events over Portugal.

2. Study area, data and method

Portugal is located on the Iberian Peninsula and is surrounded by the Atlantic Ocean in the west and south coasts, and bordered by Spain in the north and east sides. It is located between 37° and 42°N latitudes, and 10° and 6°W longitudes. In order to take into account the spatial variation of the climatological and topographical conditions and to facilitate the data analysis and interpretation, Portugal is categorized into two regions, namely (I) North of Portugal (NoP) and (II) South of Portugal (SoP) (Fig. 1a) following Koppen-Geiger Climate Classification. In general, NoP has Mediterranean climate with humid warm summers and mild rainy winters whereas, SoP has subtropical Mediterranean climate with mild winters and medium hot summers. The NoP is mountainous with several plateaus indented by river valleys, whereas the SoP is characterized by rolling plains.

2.1. Surface ozone observation

Hourly records of O₃ concentrations are obtained from 32 air quality monitoring stations, representing different type of environment (urban, suburban and rural) and type of influence (background, traffic and industrial), spatially distributed all over Portugal (Fig. 1a). All of these stations belong to the Portuguese Environmental Agency - APA network (http://www.qualar.org/). In this study, only sites with >90% data coverage for the whole period of our interest are used for analysis.

Table 1 gives detailed list of stations with information such as name of the stations, latitude-longitude-altitudes, type of environment, type of influence, operational status and data availability (%). 12 of the 32 monitoring stations are located in the NoP and the remaining 20 in the SoP. Monitoring stations are well scattered in the respective regions as shown in Fig. 1a, but are mainly clustered in and around Porto in the NoP and Lisbon in the SoP, the two biggest metropolitan areas in the respective regions.

2.2. Criteria to identify the NSO enhancement events

In this study, four distinct events of NSO enhancement (Table 2) were identified to investigate the repetitive occurrence of NSO events over the same geographical area (Portugal), based on the following criteria:
1. NSO concentration $>$ 80 $\mu$g/m$^3$ at multiple stations: NSO concentration exceeded 80 $\mu$g/m$^3$ at 5, 6, 13 and 15 stations in event 1 to event 4 respectively out of 30 stations used in the study, covering a large geographical area (Portugal).

2. Month of occurrence, duration and intensity of the events: At least one NSO enhancement event per month of the winter season was chosen i.e one in November, one in December and two in January. The choice of one event per month was made keeping in mind that Portugal has a variety of synoptic and meteorological conditions during the winter season. Also, the duration of the event (varying between 1 night [event 3] to 6 nights [event 2]) and its intensity (with maximum average NSO concentration of 79 $\mu$g/m$^3$ in the SoP) were considered.

### 2.3. Model description

A non-hydrostatic, compressible WRF regional climate model (Version 3.7.1; Skamarock et al., 2008) was used for the simulation of atmospheric processes during NSO enhancement events. Fig. 1b shows three two-way nested domains with terrain height and grid spacing (grid points) of 9-km ($400 \times 400$), 3-km ($652 \times 553$) and 1-km ($751 \times 1000$). The outermost domain is large enough to capture any synoptic activity contained within the domain boundaries. A large spatial outermost domain also provided degrees of freedom to develop its own synoptic and mesoscale circulations. The model had 40 sigma vertical levels from the surface to 50 hPa.

The innermost (1-km) domain covers continental Portugal and adjoining ocean. The three dimensional initial atmospheric fields and the time varying boundary conditions are taken from the NCEP FNL data available at 1-degree latitude-longitude resolution and at 6 h interval (http://rda.ucar.edu/datasets/ds083.2/). Sea surface temperatures are updated with 6-hourly intervals using NCEP Real-time SST archives (ftp://polar.ncep.noaa.gov/pub/history/sst). Simulations were conducted with daily initializations at 1200 UTC and integrated up to a 36-h lead-time for each set of events. The first 12-h time period is considered as a spin up time and the subsequent 24 h are considered for analysis till the end of simulation period (Pan et al., 1999; Qian et al., 2003; Lucas-Picher et al., 2013; Langodan et al., 2014, 2015; Viswanadhapalli et al., 2016). The model outputs are generated every 15 min interval for the inner domain. The terrain, land use and soil data are interpolated to the model grids from USGS global elevation, 24 category USGS vegetation data and 17 category FAO Soil data with suitable spatial resolution (30 s) for surface boundary conditions. The study uses the full-suite of model physics parameterizations which are presented in Table S1 (Supplementary material). Because of the versatility of the WRF model usage in simulating atmospheric processes at multiple spatial resolutions (meso-scale at ~50 km to local scales at ~50 m) (Heikkila et al., 2011; Sharma and Huang, 2012; Talbot et al., 2012; Conry et al., 2015), we performed WRF model simulations at 1-km horizontal resolution to explicitly resolve convection and vertical velocity to study NSO enhancement events.

### 3. Results and discussion

#### 3.1. Model inter-comparisons with observations

The model simulated air temperature at 2m altitude and wind speed at 10m which were compared with observed temperature (Fig. 2a) and wind speed (not shown here) using data from 17 weather stations belonging to the Portuguese Institute for Sea and Atmosphere (IPMA). Fig. 2a compares the diurnal variations of spatial averaged surface air temperature at 17 stations with simulated surface air temperature for all four events (Table 2). For all events, diurnal variations of observed temperature at 1 h interval were reasonably well reproduced by WRF. However, in events 1 and

**Fig. 1.** (a) Map of Portugal with land use categories and 32 ozone pollution monitoring stations (black dots) (12 in the North of Portugal [NoP] and 20 in the South of Portugal [SoP]) and 17 meteorological stations (blue dots). The red line shown in the map bifurcates Portugal into NoP and SoP; (b) WRF model nested domains: d01 as outermost domain with 9-km grid resolution, intermediate d02 with 3-km resolution, and innermost d04 domain with 1-km resolution.
3 simulated temperature minima where lower than the observed temperature. Fig. 2b shows the scatter plots between spatially averaged observed and simulated temperatures for all four events. The root mean square error (RMSE) and correlation coefficient were calculated and were found to be in the range of 0.87°C - 1.60°C and 0.94–0.97, respectively. In general, these results indicate that simulated temperatures compared well with the observed temperatures thus, the model setup can be used for detailed analysis of the specific atmospheric mechanisms responsible for the four selected NSO enhancement events.

3.2. NSO enhancement events

Four distinctive and prominent NSO enhancement events over Portugal were examined. In all the four events, NSO enhancement was observed at multiple monitoring stations in the winter months of year 2000–2010. The duration of the NSO enhancement events lasted between 2 and 6 nights depending on the local and on the synoptic conditions over Portugal during the event. In the analysis that follows, all O3 concentration values including NSO concentration values are average of 20 monitoring stations from the SoP and of 12 monitoring stations from the NoP regions respectively, unless otherwise stated. All the time notations are in UTC, which also happens to be local time in Portugal during winter.

To understand the influence of different atmospheric conditions and the transport processes responsible for NSO enhancements, various simulated meteorological variables were selected for the analysis of each one of the four events. The chosen model simulated outputs were: horizontal wind speed and direction and sea level pressure at the synoptic scale; vertical wind, potential temperature, horizontal wind speed and direction at various vertical levels at mesoscale. The Beaufort nomenclature is used in the analysis of wind speed.

3.2.1. January 2006 event

The first event considered in this study, started at around 2000 UTC of 5 Jan 2006 and lasted till 0400 UTC of the 7 Jan 2006 (Fig. 3). In the afternoon of 5, before the start of the event, the daytime spatially averaged peak O3 concentration reached the value of 50 ± 12 µg/m3 (hereafter numbers following ‘±’ is for standard
deviation) in the SoP and 36 ± 22 μg/m³ in the NoP. In the evening of the same day, just before the start of the event, the spatially averaged O₃ concentration reached the minimum value of 36 ± 24 μg/m³ in the SoP and 21 ± 22 μg/m³ in the NoP. After sunset, in the absence of photochemical production of O₃, the NSO concentration should stay low.

However, during the late evening of the 5 Jan, the O₃ concentration started increasing again and it reached secondary maxima next day early morning in both regions (70 ± 10 μg/m³ in the SoP and 69 ± 11 μg/m³ in the NoP). The observed O₃ concentration increase was 34 μg/m³ in the SoP and 48 μg/m³ in the NoP compared to the evening minima. After reaching secondary maxima, the O₃ concentration started to decrease and reached minima at around 0800 UTC for both the regions. The observed NSO enhancement shows a bimodal structure in the diurnal variation of O₃. On the 6 Jan at 0500 UTC, the NSO concentrations were higher than the peak O₃ concentration observed on the 5 Jan afternoon. The maximum NSO concentration recorded in the SoP region during this event was at Monte Velho (rural background) monitoring site (88 μg/m³), however high NSO concentration (81 μg/m³) was also observed at Mem Martins (urban background) monitoring site along with other urban sites. Similarly, maximum NSO concentration recorded in the NoP region was at Fornelo do Monte (rural background) monitoring site (85 μg/m³), but at the same time several urban and suburban sites observed high NSO concentration (>70 μg/m³). On the last night of the event, the NSO concentrations were less than the ones on the 6 early morning over the SoP and subsided over the NoP. In Fig. 3, it can be noticed that apart from bimodal structure in the diurnal variation of O₃, spatial variability (standard deviation) of O₃ concentration in the diurnal variation also shows large changes. The most interesting point worth noting is the low value of the standard deviation, indicating uniform high NSO concentration over a large part of Portugal, emphasizing the large spatial coverage and high intensity of this event. The reasonable explanation for the observed high NSO concentration with a secondary peak after midnight has to be transport processes, as ozone production ceases at nighttime.

During this event, the synoptic situation is characterized by the passage of a cold frontal system with the associated low pressure centered in the Bay of Biscay, north of Iberian Peninsula (Fig. 4a).

Fig. 2. (a) Averaged diurnal variation of 2m temperature for all four events. Black squares with line indicate observations and red dots with line are model simulations. (b) Scattered diagram of 2m observed verses model simulated air temperature for all four events. R indicates the correlation coefficient and RMSE is the root mean square error. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 3. Averaged diurnal variation of O₃ concentration on 5–7 Jan 2006 at 30 air pollution monitoring stations (12 stations from north of Portugal and 18 stations from south of Portugal).
Along the Portuguese coast, the large scale circulation is from Northwest, bringing maritime air (Fig. 4b). Both the height-latitude as well as the height-longitude cross-sections (Fig. 4c to i) showed strong downdraft over both the SoP and the NoP regions. The downdrafts had a depth of over 3 km and were compensated by the existence of updrafts over other areas in the same region, under an unstable frontal environment. Following the motion of the system, the location of these vertical circulations changed overnight, creating a well-mixed low troposphere. This mixing process brought ozone rich upper air, down to the surface. Changes in the vertical winds were accompanied by trough and ridge regions of potential temperature (black lines in Fig. 4c to i) and strong vertical wind was observed on potential temperature trough regions. At around 0400 UTC on the 6 Jan, the simulated downdrafts over both the SoP and the NoP regions were greater than 1 ms⁻¹ in some columns from the surface up to 3 km and above with high variability in the potential temperature (Fig. 4c to i) with gale to strong-gale NW horizontal winds (Fig. 4b). The NW horizontal winds were observed over the Atlantic Ocean and over Portugal, which suggests that the horizontal transport of vertically descended O₃ over the Atlantic Ocean along Portuguese coast occurred in the post cold front sector. On 7 Jan at 0300 UTC, the SoP experienced again a small NSO enhancement (with maximum NSO concentration of 50 μg/m³) whereas no NSO enhancement was observed over NoP. This supports the hypothesis that the NSO enhancement on the last night of this event was due to the combination of downdraft of the air behind the passage of a cold front and horizontal transport mechanisms over a large area.

3.2.2. December 2006 event
The second event was the longest one compared to the remaining three events analyzed in this study, starting on the evening of 1 Dec 2006 and continued till the morning of 7 Dec 2006 (Fig. 5). During this event, the maximum average NSO
concentrations were $>60 \, \mu g/m^3$ on 5 nights and 4 nights out of 6 nights respectively over the SoP and NoP region. On the nights of the 3 Dec and the 6 Dec, the average NSO concentrations were comparatively low with a high standard deviation over the SoP and the NoP. Further analysis of NSO concentration observed on 3 and 6 Dec at each station revealed that high NSO concentrations were
also observed at almost all the stations but at different time of the night resulting in low average NSO concentrations for the entire night period with high standard deviation values.

The synoptic situation was characterized by the passage of a moving surface trough, elongated over Portugal (Fig. 6a). The convergence line associated to the trough separates a region of northwestern winds, in the west sector, and another one of southwestern winds, in the east sector. The large-scale atmospheric flow pattern shows the presence of two high-pressure systems on both east (land area) and west (ocean) sides of Portugal (Fig. 6a). The nights with higher NSO values were characterized by the passage of the convergence line over the coastal regions on the 2 Dec during the midnight, 5 Dec in the early morning and on 6 Dec in the late evening, or by the existence of an instability line on the 4 Dec. The nights with higher NSO values were characterized by the passage of the convergence line over the coastal regions on the 2 Dec during the midnight, 5 Dec in the early morning and on 6 Dec in the late evening, or by the existence of an instability line on the 4 Dec. The downdrafts were greater than 1 ms$^{-1}$ on the 2 Dec and showed high day-to-day variability from the 2 Dec to the 6 Dec late night. The downdraft subsided on the 7 Dec early morning to 0.05 ms$^{-1}$ over the entire Portugal.

This type of synoptic-scale system enhanced the wind speed over Portugal and was persisted for a long period. Fig. 6b shows a narrow strip of the downdraft which was observed over the Atlantic Ocean along Portugal, between 37.5° N till 38.7° N, which continued along the coast of Portugal with higher intensity till 40.8° N. Fig. 6c to h shows simulated downdraft with intensity slightly higher than 1 ms$^{-1}$ in several narrow regions extending from the surface up to 3 km altitude and a steep trough in the potential temperature. The recurrent occurrence of prolonged NSO events with high intensity, like this one, may likely be harmful for flora and fauna (Musselman and Massman, 2000; Musselman and Minnick, 2000) and for local population.

3.2.3. November 2007 event

The third event, which occurred on the 8 and 9 Nov 2007, was the smallest but the severest of the four events analyzed in this study (Fig. 7). On 8 Nov at 2000 UTC, the O$_3$ concentrations were 25 $\pm$ 25 $\mu$g/m$^3$ and 24 $\pm$ 35 $\mu$g/m$^3$, respectively over the SoP and the NoP regions. On the 9 Nov at 0400 UTC, O$_3$ concentration started to increase over the SoP and reached a maximum concentration of 83 $\pm$ 30 $\mu$g/m$^3$. NSO concentrations, above 100 $\mu$g/m$^3$ were observed at 7 out of 15 stations in the SoP, with the highest value of NSO concentration of 119 $\mu$g/m$^3$ recorded at the Odivelas site, Lisbon. Data from 2 stations located in SoP were not available during this event. However, over the NoP, the O$_3$ concentration remained the same throughout the night (more or less the same O$_3$ concentration observed at 2000 UTC, on 8 Nov) with only 3 stations recording values more than 50 $\mu$g/m$^3$, with the highest value of NSO concentration of 100 $\mu$g/m$^3$ recorded at the Fornelo do Monte site in the central Portugal.

Fig. 8a shows the synoptic scale horizontal winds (m/s) and the sea level pressure at 0000 UTC of 9 Nov 2007. The simulated downdraft represented in Fig. 8b showed a narrow region in the horizontal plane with strong vertical winds at 1.5 km altitude over the Atlantic Ocean (from North-west corner till central costal Portugal) along with NW wind direction. The vertical winds in the same narrow region moved northward between 0100 UTC to 0330 UTC, along with a change of the wind direction from NW to northerly (Fig. 8c and d). The simulated downdraft over Portugal was slightly higher than 1 m/s-1 in several narrow regions extending from 3 km altitude down to the surface with a steep trough in the potential temperature (Fig. 8e to k). The combination of horizontal and vertical cross-sections showed a clear pattern which suggests that downdraft started over the Atlantic Ocean and moved towards costal Portugal. During the same period, a change in the wind direction from northerly to northwesterly was noticed, indicating horizontal transport of vertically descended ozone rich air from free troposphere from over Atlantic Ocean towards continental Portugal, particularly towards the SoP region.

3.2.4. January 2009 event

The fourth event lasted for 4 days from 12 to 15 Jan 2009 (Fig. 9). On 12 Jan at 1900 UTC, the observed minimum O$_3$ concentrations were 21 $\pm$ 23 $\mu$g/m$^3$ (SoP) and 29 $\pm$ 27 $\mu$g/m$^3$ (NoP). After 1900 UTC, the O$_3$ concentrations started increasing and at 2200 UTC, the O$_3$ concentration reached $\sim$44 $\mu$g/m$^3$ over both the SoP and the NoP. The O$_3$ concentration further continued to increase at a faster rate over the SoP, compared to NoP, and reached up to 70 $\pm$ 17 $\mu$g/m$^3$ at midnight, an increase of $\sim$6 $\mu$g/m$^3$ in the course of 2 h during the night. The NSO concentration reached the peak value of 79 $\pm$ 17 $\mu$g/m$^3$ on 13 Jan at 0400 UTC over SoP, an increase of more than 375% compared to the evening minimum observed on the 12 Jan at 1900 UTC. On the other hand, over the NoP, the O$_3$ concentration further continued to increase gradually from $\sim$44 $\mu$g/m$^3$ observed at 2200 UTC on 12 Jan, reaching a maximum O$_3$ concentration of 61 $\pm$ 13 $\mu$g/m$^3$ at 0400 UTC on the 13 Jan.

The synoptic scale horizontal winds and the sea level pressure are shown in Fig. 10a. Model simulations showed the formation of a low level jet along the coast of Portugal on the evening of 12 Jan which persisted till late morning (Fig. 10b to 10e). Large-scale analysis showed that this was a pre-frontal low-level jet (LLJ) (Fig. 10a). The frontal convergence zone separates two wind patterns, one of northwest winds and another one of southwest winds. The cold front moves from northwest to southeast. In the warm sector, the strong southwest LLJ along the coast of Portugal reaches intensities of about 20 ms$^{-1}$, ahead of the cold front. The movement of the system from the northwest sector to southeast sector of Portugal took about 4–6 h. The shear associated with the passage of the LLJ enhances turbulent mixing (Fig. 10f to m) and weakens the decoupling between the residual layer and the stable nocturnal boundary layer (Hu et al., 2013). This allows ozone rich air from residual layer and free troposphere to actively mix with the surface air, causing NSO enhancement at the surface. On 13 night there was no NSO enhancement. Analysis of the simulated vertical wind was performed for the 14 early morning when there was no NSO enhancement and found that vertical wind reached its minimum value over SoP and NoP. However, on 14 evening, after reaching the evening minima, the O$_3$ concentration again started to increase and
reached a NSO maximum of $67 \pm 16 \mu g/m^3$ (SoP) and of $58 \pm 7 \mu g/m^3$ (NoP) after midnight.

### 4. Conclusions

In this study we have identified and studied four events of NSO enhancement over the same geographical region (Portugal) over a period of 10 years. The WRF model was used to simulate atmospheric processes at high resolution (1 km in the horizontal) and to identify different atmospheric transport mechanisms which may have likely been responsible for the NSO enhancements observed over Portugal.

The first NSO enhancement event was caused by enhanced vertical mixing as a result of the passage of a cold front. Reitebuch et al. (2000) also reported the passage of a cold front as responsible for NSO enhancement observed over North Rhine-Westphalia, Germany, based on air quality and meteorological observations, without model simulations. During the second event, the existence of two high-pressure systems on both sides (east (land area) and west (ocean) sides) of Portugal with the passage of a moving surface trough, elongated over Portugal, with associated strong horizontal wind speed and vertical shear, persisted for a long period, causing downdrafts and NSO enhancement which lasted for several days. Similar prolonged period of high ozone concentration with multiple high NSO events was also observed at San Bernardino, Alpine valley (Prevot et al., 2000), but not due to same atmospheric mechanisms. The third event shows that, under strong vertical winds in a narrow horizontal region, the NSO enhancement can be intense and even exceed the daytime $O_3$ concentrations. This event also shows the occurrence of NSO enhancement due to the combination of vertical mixing and horizontal transport mechanisms over a large area. Eliasson et al. (2003) also reported that the combination of vertical mixing and horizontal transport mechanism was responsible for NSO enhancement over the city of

---

**Fig. 8.** (a) Horizontal winds ($m/s$) at 850 hPa level along with the sea level pressure (hPa, shaded) at 9 km model resolution at 0000 UTC of 9 Nov 2007; (b) to (d) Horizontal winds at 1.5 km (0100 UTC), 1 (0200 UTC), and 0.7 (0330 UTC) height along with vertical velocity (shaded) at 1 km model resolution; (e) to (g) Height-latitude cross section of vertical velocity (shaded) and potential temperature (contours) along 350.5, 350.6 and 350.8$^\circ$; and; (h) to (k) Height-longitude cross section of vertical velocity (shaded) and potential temperature (contours) along 41.2$^\circ$N, 41.0$^\circ$N, 40.8$^\circ$N and 39.5$^\circ$N at 0345 UTC of 9 Nov 2007.
Göteborg, but it occurred during summer over a smaller geographical area (single city) and was based on air quality and meteorological observations, without model simulations. The enhancement of NSO during the fourth event was due to the formation of a LLJ along the Portuguese coast, which is associated with vertical mixing below the jet stream. Klein et al. (2014) also studied the role of LLJ on vertical mixing and downward transport of O3 resulting in the NSO enhancement event, using observations and model simulation, over the Oklahoma metropolitan area, which is a landlocked area, more than 600 km from nearest coast.

NSO enhancement event is considered as an anomaly and highly variable in time and space (Löffler-Mang et al., 1997). The aforementioned NSO enhancement events, that occurred in different geographical areas and studied by Reitebuch et al. (2000), Prevot et al. (2000), Eliasson et al. (2003) and Klein et al. (2014) were considered as special events and single atmospheric mechanism was proposed to explain each one of them. However, this study of NSO enhancement events, using long term (2000–2010) observations as well as model simulations, for the first time shows that NSO enhancement events may occur (a) frequently over the same geographical area (in this case over Portugal) (b) with large spatial-temporal coverage (c) with high O3 concentration values (d) during the winter months and (e) due to one and/or combination of

---

Fig. 9. Averaged diurnal variation of O3 concentration on 12 to 15 Jan 2009 at 31 air pollution monitoring stations (12 stations from north of Portugal and 19 stations from south of Portugal).

Fig. 10. (a) Horizontal winds (m s\(^{-1}\)) at 850 hPa level along with the sea level pressure (hPa, shaded) at 9 km model resolution at 0000 UTC of 13 Jan 2009; (b) to (e) Horizontal winds at 0.3, 0.5, 0.7 and 1 km height along with vertical velocity (shaded) at 1 km model resolution at 0345 UTC of 13 Jan, 2009; (f) to (i) Height-latitude cross section of vertical velocity (shaded) and potential temperature (contours) along 351°, 351.1°, 351.2° and 351.3° respectively at 0345 UTC of 13 Jan 2009, and; (j) to (m) Height-longitude cross section of vertical velocity (shaded) and potential temperature (contours) along 41.0° N (0345 UTC), 39.3° N (0230 UTC), 38.9° N (0345 UTC) and 38.5° N (0100 UTC) of 13 Jan 2009.
different atmospheric mechanisms, at both synoptic and/or mesoscale. Moreover, large scale flow patterns that favor vertical downwcasts seem to play a major role in the NSO enhancement events.

Further in-depth study of NSO enhancement with observed data and model simulations is required to fully understand the processes and implications, particularly with observed increasing trend in the background tropospheric ozone (Logan et al., 2012) due to climate change.
