Abstract—The systematic storage in neural networks of prior information to be used in the design of various control subsystems is investigated. Assuming that the prior information is available in a certain form (namely, input/output data points and specifications between the data points), a particular neural network using Gaussian nonlinearities and a corresponding parameter design method are introduced. The proposed neural network addresses the issue of effectively using prior information, and its use is illustrated in an implementation of a control law scheduler.

1. INTRODUCTION

In many practical control problems, there exists substantial prior information about the various subsystems of the control system. In modeling these subsystems via neural networks, it is desirable to incorporate this prior knowledge into a neural network. A particular neural network architecture and an associated design methodology are presented in this paper to accomplish this for certain types of prior knowledge. Using this procedure, prior knowledge is directly and systematically stored in the neural network with no training. This has the advantage of having the information in a neural network form, which can be quickly accessed once implemented in hardware.

With the proposed neural network architecture, the following control problems can be addressed: dynamical system (plant and controller) modeling, fault detection and identification, information extraction, and control law scheduling. Of these, the implementation of control law scheduling via the proposed neural network is chosen to illustrate both the neural network and its design procedure. It is assumed that a set of training points and certain specifications for the behavior between the training points are provided. With this training set, the neural network is designed to satisfy the specifications for the interpolation between the operating points. The proposed neural network has two layers of weights with Gaussian nonlinearities for the hidden layer and linear functions for the output layer. The connection of the hidden layer to the output layer and the specific choices for the weights are unique aspects of this neural network design approach.

For the neural network scheduler implementation described in this paper, the neural network is first given information on the system's operating conditions or its environment and then supplies control law switching information to the controller. As depicted in Figure 1, the neural network's inputs are the inputs and outputs of the plant together with the reference signal. The output

*Current address: 1801 Crystal Drive, Apt. 313, Arlington, VA 22202, U.S.A.
The authors wish to acknowledge the partial support of the Jet Propulsion Laboratory under Contract No. 957856.
of the neural network is the control law adjustment signal sent to the controller. The neural network's inputs are not restricted to these signals; other signals such as the plant's states, derivatives, environmental conditions, or delayed values of any of these can be used as inputs to the neural network. Basically, any signal that is designed into the operation of the scheduler is used as an input to the neural network. Furthermore, the plant and controller can operate in either continuous or discrete time. If the neural network is implemented in analog hardware, both the plant and the controller can operate in continuous time. However, if the neural network is to be implemented in software, both the plant and the controller need to be discrete or discretized versions of continuous ones. In either case, the designing of the neural network as discussed in this paper remains unchanged.

![Figure 1. Neural network used as a scheduler.](image)

The Gaussian neural network design procedure presented in this paper represents one possible approach for satisfying the relationship between the input/output pairs of the training set. Clearly, there exist other methods to (mathematically) describe the desired curve and solve the problem; for instance, polynomial or spline approximations can be used to represent the desired function. An advantage of using the neural network approach described here instead of one of these schemes is that the actual construction of the neural network in hardware would utilize the inherent parallelism of the neural network, and hence, result in a fast processing time. Compared to other neural network techniques, the design scheme here has several advantages. For one, there is no training required; only the design time needed to choose the appropriate function parameters (i.e., the specifications for the interpolation between the training pairs) is necessary. Also, exact control of the generalization between the training points is guaranteed via the design scheme. Furthermore, the number of layers and the number of neurons needed to correctly implement the desired function are known precisely. Instead of applying the Gaussian neural network as a scheduler as described here, the application of the Gaussian neural network in the control cycle is discussed in [1]. Neural network architectures similar to the Gaussian neural network described here include those employing radial basis functions, and a comparison with these is discussed later. For information on radial basis functions, the interested reader is referred to [2–5].

In Section 2, the type of scheduler implementation considered in this paper is defined. The implementation using a Gaussian neural network is presented for both single-input and multi-input operating points in Sections 2.1 and 2.2, respectively, and discussed in terms of equidistant and nonequidistant operating points in Sections 2.1.1 and 2.1.2, respectively. In Section 2.1.3, a comparison to other neural network design methods is included. Finally, examples demonstrating the neural network scheduling implementation presented in this paper are supplied in Section 3.

## 2. IMPLEMENTATION USING

A GAUSSIAN NEURAL NETWORK

The Gaussian neural network implementation of a scheduler is divided into two cases: single-input and multi-input. The single-input is further divided into equidistant operating points and nonequidistant operating points.
2.1. Single-Input Gaussian Neural Network Scheduler

In this section, a neural network is constructed to implement a scheduler with operating points defined for a single input. For each operating point, the scheduler provides one or more parameter values to be used in controlling the system. For the given values of the scheduler, let \( v(j) \) denote the \( j^{th} \) operating point for \( 1 \leq j \leq p \), and let \( v \in \mathbb{R}^{p\times 1} \) denote the vector of all operating points arranged in ascending order, where \( v(j) > v(j-1) \) for \( 2 \leq j \leq p \). Let \( d_i(j) \) denote the \( i^{th} \) desired output (i.e., the given control law parameter values) of the scheduler for the \( j^{th} \) operating point for \( 1 \leq i \leq n \) and \( 1 \leq j \leq p \), and let \( d(j) \in \mathbb{R}^{n\times 1} \) and \( D \in \mathbb{R}^{p\times n} \) denote the vector for \( 1 \leq j \leq p \) for the matrix of desired outputs, respectively. Thus, the \( p \) pairs \( \{v(j), d(j)\} \) are the given operating points. For the neural network, let \( u \in \mathbb{R}^{1\times 1} \) denote the neural network's input, and let the neural network have multiple outputs denoted by \( z \in \mathbb{R}^{n\times 1} \). For a specific input \( u \), let \( z_i(u) \) for \( 1 \leq i \leq n \) and \( z(u) \) denote the output of the neural network.

In constructing the neural network to implement the designed scheduler, three specifications are made:

(i) If \( u = v(j) \), then \( z(u) = d(j) \).
(ii) If \( u \in [v(j) - \varepsilon_{j-1}, v(j) + \varepsilon_{j+1}] \) and \( u \neq v(j) \), then \( z_i(u) \in [d_i(j) - \gamma_{ij-1}, d_i(j) + \gamma_{ij+1}] \).
(iii) If \( u \in [v(j), v(j + 1)] \), then \( z_i(u) \in [d_i(j), d_i(j + 1)] \).

As an example, Figure 2 illustrates one way in which these specifications can be viewed. The dots correspond to the operating points and the given controller parameter, and according to specification (i), the interpolation curve must pass through these points. The boxes surrounding the dots correspond to the boxes described in specification (ii), and the boxes between the dots correspond to the bounding of the interpolation curve per specification (iii). The interpolation curve must pass correctly through both sets of boxes. Clearly, there exist numerous curves that satisfy these three specifications. With the design scheme described here for the parameters of the neural network, a particular class of curves is achieved that satisfy these specifications, and of the three specifications, (i) and (ii) can be satisfied precisely using the proposed procedure, and (iii) can be approximately satisfied.

![Figure 2. Illustration of interpolation curve specifications.](image)

With \( z \in \mathbb{R}^{n\times 1} \), an individual output of the neural network is described by

\[
z_i = \sum_{k=1}^{h} w_{ik} g(x_k),
\]

where \( 1 \leq i \leq n \), \( w_{ik} \) is the weight of the \( i^{th} \) linear neuron in the output layer, and \( g(x_k) \) is the output of the \( k^{th} \) neuron in the hidden layer. Let \( W \in \mathbb{R}^{h \times n} \) denote the matrix of weights for the output layer. Since the scheduler has a single input describing its operating points, the neural network requires only a single input \( u \in \mathbb{R}^{1\times 1} \). The output of the \( k^{th} \) Gaussian neuron in the neural network's hidden layer described by

\[
g(x_k) = \exp(-x_k^2)
\]
and
\[ x_k = s_k (v - c_k)^2, \] (3)

where \(1 \leq k \leq h\), \(g : \mathbb{R} \rightarrow \mathbb{R}\) is the nonlinearity of the hidden layer neurons and the Gaussian function with the variable \(\alpha\) describing its curvature, \(s_k\) is the weight (or "width" of the Gaussian function), and \(c_k\) is the bias (or "center" of the Gaussian function). Let \(s \in \mathbb{R}^{h \times 1}\) denote the vector of widths, and \(c \in \mathbb{R}^{h \times 1}\) denote the vector of centers. With \(\alpha = 1\), the traditional bell-shaped curve is achieved, but by allowing \(\alpha\) to vary, a class of curves is possible, which allows for greater flexibility in the design of the interpolation curve. Thus, for a particular neural network implementation of a scheduler, the parameters \(W, s, c, \alpha\) need to be selected. The choosing of the Gaussian neural network parameters is divided into two cases: when the operating points are equidistant and when they are nonequidistant.

2.1.1. Design with equidistant operating points

For the first case, the operating points \(v(j)\) for \(1 \leq j \leq p\) are considered to be equidistant. For the \(p\) operating points, assume the distance between each operating point is \(T\). The number of hidden layer Gaussian neurons is set equal to the number of operating points, that is, \(h = p\). This choice is not unreasonable since for many scheduler applications, the number of operating points is not unusually large. The center \(c_k\) for the \(k^{th}\) neuron is set equal to the operating point value for the \(k^{th}\) operating point
\[ c_k = v(k), \] (4)

for \(1 \leq k \leq h\). Since \(c_k\) corresponds to the center of the Gaussian nonlinearity, setting \(c_k\) equal to the operating point parameter corresponds to placing the center of each Gaussian neuron at each operating point and allows for a localized effect at the output of these neurons with the appropriate choice for each width \(s_k\).

To aid in satisfying specifications (ii) and (iii), the widths \(s\) are chosen such that (1) can be approximated by
\[ z_i(u) \approx \sum_{k=j}^{j+1} w_{ik} g(x_k) \] (5)

when \(u \in [v(j), v(j+1)]\). This implies that the tails of the Gaussian nonlinearities \(g(x_k(u))\) for \(k \neq j\) and \(k \neq j+1\) are small compared to those for \(k = j\) and \(k = j+1\) when \(u \in [v(j), v(j+1)]\). The approximation of (5) also implies that the Gaussian neuron with its center \(c_k\) closest to the input \(u\) has a larger response compared to the other Gaussian neurons signifying that the input is closest to the \(k^{th}\) operating point
\[ g(x_k(u)) \geq g(x_j(u)), \] (6)

for \(1 \leq f \leq h\) and for \(u \in [v(k) - \Delta_{k-1}, v(k) + \Delta_k]\), where \(\Delta_k\) is defined such that \(g(x_k(v(k) + \Delta_k)) = g(x_{k+1}(v(k) + \Delta_k))\). With (6), the localized effect of the hidden layer neurons is preserved. Also, the interpolation curve passing through a box specified by specification (ii) assumes the general shape of the output of the \(k^{th}\) Gaussian neuron if \(\epsilon_{k-} \leq \Delta_{k-1}\) and \(\epsilon_{k+} \leq \Delta_k\). To further aid in satisfying specification (iii), the widths \(s\) are chosen such that
\[ \sum_{k=1}^{h} g(x_k(u)) \approx 1, \] (7)

for \(u \in [v(1), v(p)]\). In conjunction with (5) and (6), (7) implies that, for \(u \in [v(k), v(k+1)]\), the sum of the outputs of \(g(x_k(u))\) and \(g(x_{k+1}(u))\) is constant, and the \(k^{th}\) Gaussian neuron contributes more to the sum when \(u\) is close to \(v(k)\) and less when it is closer to \(v(k+1)\). Since all the operating points are spaced apart by an equal distance \(T\), the width \(s_k\) for each neuron
is selected equivalent such that each neuron has an equal response halfway between any two neurons. By setting \( g(x_k) \) in (2) equal to 0.5,

\[
s_k = \frac{4g^{-1}(0.5)}{\tau^2},
\]

where \( 1 \leq k \leq h \) and \( g^{-1}(r) := (-\ln(r))^{1/\alpha} \). Unfortunately, due to the nonlinear nature of the Gaussian function of (2), using (8) to determine \( s \) does not insure that (5), (6), and (7) are satisfied exactly, but rather are satisfied approximately; with (8), a good approximation to a constant unit signal is achieved as described by (7), and through experimentation, a possibly more appealing signal may be found by slightly adjusting the widths.

Due to the use of the Gaussian nonlinearity and the choice of function's center and width for each of the hidden layer neurons, the output of the neural network is close to 0 if the input is outside the region of the operating points. In other words, if \( u \ll v(1) \) or \( u \gg v(p) \), then \( z \equiv 0 \). This is a drawback if a value is needed from the scheduler for all possible inputs. However, this behavior could be used in a fault detection scheme to identify when the inputs have exceeded the design domain.

The choice of the exponent \( \alpha \) in (2) clearly affects the shape of the interpolation curve. In Figure 3, \( g(x_k) = \exp(-x_k^2) \) is shown for various values of \( \alpha \) with \( c_k = 0 \) and \( s_k = 1 \). As can be seen, the Gaussian curve begins to better approximate a unit pulse function as \( \alpha \) is increased. By appropriately choosing \( \alpha \), the interpolation curve can be designed to pass though the box defined in specification (ii). The exponent \( \alpha \) also affects how well (7) is satisfied and the choice of the widths \( s \) in (8). It is suggested here that, in general, \( \alpha \geq 1 \). Furthermore, unless stated otherwise, it is assumed that each neuron's nonlinearity in the hidden layer has the same value for the exponent \( \alpha \). Although, by choosing different values of \( \alpha \) for different neurons, various interpolation curves are possible.

![Figure 3. Family of Gaussian-type curves for varied \( \alpha \).](image)

With the widths, centers, and the nonlinearity specified for the hidden layer, the weights for the linear output layer are chosen next. Let \( G \in \mathbb{R}^{p \times h} \) denote the output of the hidden layer neurons for each of the \( p \) operating points. Thus, the output layer weights are found by solving the following linear system of equations

\[
G W = D.
\]

Since \( G \) is square and nonsingular \( (h = p) \), (9) has a unique solution \( W \). Thus, if the neural network's input \( u \) is exactly one of the operating points, the neural network's output is exactly the desired output of the scheduler, which satisfies specification (i).
2.1.2. Design with nonequidistant operating points

For the second case, the operating points \( v(j) \) for \( 1 \leq j \leq p \) are considered to be nonequidistant. Two methods are proposed to cope with this situation: adding more Gaussian neurons to the hidden layer or using an optimization procedure to adjust the parameters of the hidden layer neurons. It is assumed that there are \( p \) hidden layer neurons with centers \( c \) chosen as in (4), and that the weights \( W \) are chosen such that (9) is a unique system insuring that specification (i) is satisfied.

First, by adding more Gaussian neurons to the hidden layer, a situation in which the centers of the Gaussian neurons are equidistant occurs. This approach is useful if some of the operating points are equidistant, and the others occur at specific intervals between the operating points. First, \( p \) hidden layer Gaussian neurons are formed with their centers equal to the operating points as specified in (4). Next, more hidden layer Gaussian neurons are added, and their centers are chosen such that the centers of the Gaussian neurons are equidistant. For example, if

\[
v = [1 \ 1.5 \ 2 \ 3 \ 4]^T
\]

is the vector of operating points, five hidden layer Gaussian neurons are formed with \( c_k = v(k) \). Two more Gaussian neurons are added with centers of 2.5 and 3.5 such that \( h = 7 \). Since all of the centers of the Gaussian neurons are equidistant and \( T = 0.5 \), the widths \( s \) are found via (8) with \( \alpha = 2 \), and \( s_k = 13.3209 \) for \( 1 \leq k \leq 7 \). With the centers and the widths selected, the exponent \( \alpha \) can be varied to further satisfy the specifications of the interpolation curve. The weights for the output layer are found by forming a linear system of equations similar to that of (9). To make the system unique, the desired output associated with each added Gaussian neuron is assigned either a specified value of a close operating point or an interpolated value from nearby operating points.

Second, instead of adding neurons based on pseudo-operating points, an optimization procedure may be used to find the Gaussian neural network’s parameters. In this paper, a gradient descent procedure is proposed to cope with the case of nonequidistant operating points and to adjust the parameters of the hidden layer. The hidden layer is constructed of \( h = p \) Gaussian neurons with exponent \( \alpha \) and with centers \( c \) equal to the operating points of the scheduler as described in (4). With the cost function

\[
F = \frac{1}{2} \sum_{j=1}^{p} \left( 1 - \sum_{k=1}^{h} g(x_k(v(j))) \right)^2 + \frac{1}{2} \sum_{j=1}^{q} \left( 1 - \sum_{k=1}^{h} g(x_k(v(j))) \right)^2,
\]

an approximate unit signal from the hidden layer as described by (7) is desired. The first sum corresponds to the neural network’s output for inputs equal to the \( p \) operating points. The second sum corresponds to the output of the neural network for \( q \) other values \( u(j) \in [v(1), v(p)] \). The particular points in the second sum are not specified in order to leave this as a design consideration. The gradients of (10) are computed with respect to \( s_k, c_k, \) or even \( \alpha, \) and the parameters of the Gaussian neural network are adjusted via an iterative gradient descent procedure. The details of this approach are in [6,7].

When the operating points are not equidistant, both of the methods proposed can also be used in combination to determine the parameters of the hidden layer Gaussian neurons. Extra neurons can first be added at desirable locations, and the gradient descent procedure can then be used to find the appropriate parameters of the hidden layer. To find the weights \( w_{ik} \) of the output layer, extra desired outputs are needed as described previously to insure that the linear system of equations described in (9) remains unique.
2.1.3. Comparison to another method

Here, the design procedure of Moody [2,3] is compared to the approach presented here. In comparing the method proposed here and Moody's method, the following are the same: \( h = p \), the centers are chosen as in (4), and the output weights as in (9). The only differences considered here are the choices of \( \alpha = 1 \) and different widths \( s \).

The design procedure proposed by Moody is presented next. To choose the centers, Moody proposes to use the standard \( k \)-means clustering algorithm since it is assumed that the number of training pairs \( p \) is large, which is not the assumption made here for the scheduling problem. However, the case when the centers are chosen equal to the training inputs as in (4) is treated in Moody's examples. The exponent \( \alpha \) of the Gaussian nonlinearities is specified as 1. The widths \( s \) are determined by a "\( P \) nearest neighbor" heuristic, which in [2] is described as using the root mean square value of the Euclidean distance to the \( P \) nearest neighbor centers to determine the widths. Using the notation here and \( P = 2 \),

\[
s_k = \frac{2}{(c_k - c_{k-1})^2 + (c_{k+1} - c_k)^2},
\]

for \( 1 \leq k \leq h \). The weights of the output layer are determined via an LMS algorithm. If \( h = p \) and the centers are chosen as in (4), the LMS iterative procedure is not needed and the unique system of (9) can be solved instead. In comparing the method proposed here and Moody's method, the following are the same: \( h = p \), the centers are chosen as in (4), and the output weights as in (9). The only differences considered here are \( \alpha = 1 \) and the widths chosen as in (11).

In [2,3], the use of gradient descent procedures to determine the neural network's centers, widths, and output layer weights are discussed. The cost function considered uses the sum of the squares of the errors

\[
F = \frac{1}{2} \sum_{j=1}^{p} (d(j) - z(v(j)))^2,
\]

which can be compared to the one proposed in (10). In (12), the neural network is assumed to have only one output, while the Gaussian neural network here may have more than one.

The application of Moody's method for selecting the neural network's parameters are recorded in [8,9], which both address the problem of fault detection and identification.

2.2. Multi-Input Gaussian Neural Network Scheduler

In this section, a neural network is constructed to implement a scheduler with operating points that vary for more than one parameter. For the given values of the scheduler, let \( v_r(j) \) denote the \( r \)-th parameter of the scheduler for the \( j \)-th operating point for \( 1 \leq r \leq m \) and \( 1 \leq j \leq p \). Let \( v(j) \in \mathbb{R}^{m \times 1} \) denote the operating point vector for \( 1 \leq j \leq p \). As described previously, \( d(j) \in \mathbb{R}^{n \times 1} \) and \( D \in \mathbb{R}^{p \times n} \) denote the vector for \( 1 \leq j \leq p \) and the matrix of desired outputs, respectively. Thus, the \( p \) pairs \( \{v(j), d(j)\} \) are the given operating points. For the neural network, let \( u \in \mathbb{R}^{m \times 1} \) denote the neural network's input, and let the neural network have multiple outputs denoted by \( z \in \mathbb{R}^{n \times 1} \). For a specific input \( u \), let \( z_i(u) \) for \( 1 \leq i \leq n \) and \( \pi(u) \) denote the output of the neural network.

The output of the Gaussian neural network is given by

\[
z_i = \sum_{k=1}^{h} w_{ik} g(x_k),
\]

where \( 1 \leq i \leq n \). The outputs of the hidden layer Gaussian neurons are described by

\[
g(x_k) = \exp(-x_k^2)
\]
and

\[ x_k = \sum_{r=1}^{m} s_{kr} (v_r - c_{kr})^2, \]

(15)

where \( 1 \leq k \leq h \). Let \( S \in \mathbb{R}^{h \times m} \) denote the matrix of widths, and \( C \in \mathbb{R}^{h \times m} \) denote the matrix of centers. Compared to the Gaussian neurons proposed by Moody [3], the widths \( s_{kr} \) in (15) vary for the different \( r \), which allows the Gaussian nonlinearity to assume an ellipsoid shape for higher dimensions of operating point parameters and not just a circular shape.

In choosing the values for the centers, widths, and the Gaussian variable \( \alpha \), it is once again desirable to satisfy the three design specifications stated in Section 2.1. In addition, the two cases considered previously for the spacing of the operating points are applicable here: when the operating points are equidistant and when they are nonequidistant. For the multi-input case, equidistance is considered for each individual direction and not as a norm over all the directions.

For the first case when the operating points are equidistant, the previous results are directly extended. A two layer neural network is formed with \( h = p \) hidden layer Gaussian neurons and output linear neurons. The center \( c_{kr} \) for each Gaussian neuron is set equal to the corresponding parameter for each operating point:

\[ c_{kr} = v_r(k), \]

(16)

for \( 1 \leq r \leq m \) and \( 1 \leq k \leq h \). With \( T_r \) denoting the distance between the two operating points for the \( r^{th} \) parameter, the width \( s_{kr} \) for each neuron is given by

\[ s_{kr} = \frac{4g^{-1}(0.5)}{T_r}, \]

(17)

for \( 1 \leq r \leq m \) and \( 1 \leq k \leq h \). The Gaussian variable \( \alpha \) is chosen to satisfy specification (ii), and the weights \( w_{ik} \) for the output layer are found by solving the unique linear system of equations in (9).

For the second case when the operating points are not equidistant, the results from Section 2.1.2 extend directly. If the operating points are well placed, extra Gaussian neurons can be added to the hidden layer such that, with the extra Gaussian neurons, the centers of all the Gaussian neurons are equidistant. Also, similar to the approach described previously, an optimization procedure may be used to determine the widths, centers, and exponents \( \alpha_k \). In addition, the combination of extra Gaussian neurons and an optimization procedure can be used to satisfy the design specifications.

As the number of parameters for the operating points increases, one potential disadvantage of adding extra neurons is the possibility for a large number of neurons to result; if extra neurons are added for a multi-input scheduler of high dimension, the size of the neural network may become unwieldy. However, for the examples provided in Section 3, this is not the case. Another drawback with this approach is that “valleys” develop in the interpolation curve due to the multi-dimensional ellipsoid described by (14) and (15). This is illustrated in Example 3.3.

3. EXAMPLES

EXAMPLE 3.1. In [10], a parameter learning method is presented and used to define the region of operation for an adaptive control system of a flexible space antenna. In one of the experiments described, an initial pulse disturbance is applied to the plant, and the adaptive controller is required to follow a zero-order reference model. The goal of the parameter learning system is to find and store values for the four adaptive controller parameters \( (\sigma_1, \sigma_2, L, \text{ and } \bar{L}) \) for varied amplitudes of a pulse disturbance (system initial conditions) such that a defined performance index based on the output of the plant is minimized. In Table 1, the values found for the controller parameters for different pulse amplitudes are repeated. Using this table, the goal here is to construct a neural network scheduler such that a smooth interpolation is achieved.
between the 9 operating points. Using the results of Section 2.1.1 for the single-input scheduler with equidistant operating points of distance $T = 0.5$, a Gaussian neural network is designed to implement the controller scheduler.

For the two-layer Gaussian neural network scheduler, the centers of the Gaussian neurons in the hidden layer are set equal to the operating points per (4)

$$c = [2.0 \ 2.5 \ 3.0 \ 3.5 \ 4.0 \ 4.5 \ 5.0 \ 5.5 \ 6.0]^T.$$  

Applying (8), the weights of the Gaussian neurons in the hidden layer are $s_k = 13.3209$ for $\alpha = 2$ and for $1 \leq k \leq 9$. With the outputs $g(x_k)$ of the individual Gaussian neurons for $1 \leq k \leq 9$ shown in Figure 4, the localized properties of the Gaussian neurons are evident; as expressed in (5) and (6), the $k^{th}$ Gaussian neuron's output is large compared to the other Gaussian neurons' outputs when the input is closest to the center of the $k^{th}$ Gaussian neuron. Forming the matrix $G \in \mathbb{R}^{2 \times 9}$ from the outputs of the hidden layer and forming the matrix $D \in \mathbb{R}^{9 \times 4}$ of the desired outputs of the neural network scheduler from the entries in Table 1, the weights $W$ for the linear neurons in the output layer are found by solving (9). Figure 5 shows the output of the Gaussian neural network scheduler for $\sigma_2$, and for comparison, the straight line approximation between the operating points is included as the dashed line. As can be seen, $z_2(k) = d_4(k)$ for $1 \leq k \leq 9$, and specification (i) is satisfied. In the regions nearby the operating points, the adaptive controller parameter values specified by the neural network scheduler are close to those specified by Table 1 satisfying specification (ii) for large $\varepsilon_2$ and small $\gamma_{ij}$. In regions between operating points, a swift yet smooth transition occurs between the value specified by Table 1, and specification (iii) is almost met. Between 4.0 and 4.5 in Figure 5, specification (iii) requires a straight line, and this is almost satisfied.

![Figure 4. Individual hidden layer outputs for Example 3.1.](image-url)
As described in Section 2.1.1, by increasing \( \alpha \), the Gaussian function begins to approximate a unit pulse function. Performing the design steps for a Gaussian neural network with \( \alpha = 20 \) (instead of \( \alpha = 2 \)), the Gaussian neural network's output for the adaptive controller parameter \( \sigma_2 \) is plotted in Figure 6 along with the straight line approximation (dashed line), and the three design specifications are satisfied.

For comparison, the design procedure suggested by Moody [2,3] is used. With \( h = p \), the centers are chosen as in (4). With \( \alpha = 1 \), the widths are chosen as \( s_k = 4 \) for \( 1 \leq k \leq 9 \). The weights \( W \) are found by solving for \( W \) in (9). In Figure 7, the neural network output for \( \sigma_2 \) is displayed along with the straight line approximation (dashed line). Specification (i) is met due to the solving of (9) for \( W \). However, specification (ii) can only be satisfied for small \( \epsilon_j \) and large \( \gamma_{ij} \), and specification (iii) is not met at all.

**Example 3.2.** In Table 2, two more disturbances and the appropriate adaptive controller parameter values found by the parameter learning system of [10] are shown. With the addition of these disturbances to those in Table 1, the operating points for the scheduler are no longer equidistant, and the results of Section 2.1.2 are applicable. To cope with the disturbance amplitudes not being equidistant, extra Gaussian neurons are added to the hidden layer, and the vector of centers is

\[
c = [2.00 \ 2.25 \ 2.50 \ 2.75 \ 3.00 \ldots 6.00 \ 6.25 \ 6.50 \ 6.75 \ 7.00]' .
\]
Applying \((8)\) with \(T = 0.25\) and with \(\alpha = 2\), the weights of the Gaussian neurons in the hidden layer are \(s_k = 53.2835\) for \(1 \leq k \leq 21\). Adding pseudo-desired outputs, the matrices \(G \in \mathbb{R}^{21 \times 21}\) and \(D \in \mathbb{R}^{21 \times 4}\) are formed, and the unique linear system of equations in \((9)\) is solved for \(W\). The Gaussian neural network’s output for \(\sigma_2\) is shown in Figure 8. Once again, specification (i) is satisfied exactly, and specification (iii) is satisfied approximately. Specification (ii) can be satisfied for smaller boxes compared to those boxes possible when the points are equidistant, as in Example 3.1.

**Example 3.3.** In [11], linear models of an F100 engine are developed for various flight points based on altitude and mach number. In Table 3, six of these flight points are listed with fictitious controller parameters, and in Figure 9, these six are diagrammed. It is desired to develop a neural network scheduler for interpolation between these flight points. The scheduler desired is a multi-input one, and the results of Section 2.2 are applicable. Since the operating points are
nonequidistant, the method of adding extra Gaussian neurons to the hidden layer is chosen, and six extra Gaussian neurons are added to achieve equidistance. With \( r = 1 \) corresponding to the altitude and with \( r = 2 \) corresponding to the mach number, the matrix of centers is

\[
C' = \begin{bmatrix}
10 & 10 & 10 & 20 & 20 & 20 & 30 & 30 & 30 \\
0.50 & 0.75 & 1.00 & 1.25 & 0.50 & 0.75 & 1.00 & 1.25 & 0.50 & 0.75 & 1.00 & 1.25
\end{bmatrix}
\]

and the vector of outputs for equation (9) is

\[
d = [1 \ 2 \ 3 \ 4 \ 1 \ 1 \ 1 \ 1 \ 1 \ 5 \ 6 \ 6]' \]

Applying (28) with \( \alpha = 20 \), \( T_1 = .25 \), and \( T_2 = 10 \), \( s_{k1} = 62.8378 \), and \( s_{k2} = 0.0393 \) for \( 1 \leq k \leq 12 \). Solving (9) for \( w \), the interpolation curve is shown in Figure 10. The lowest corner corresponds to the point \((8, 0.4)\), the most left corner to \((32, 0.4)\), and the most right corner to \((8, 1.35)\). Specifications (i) and (ii) are clearly satisfied, but due to the elliptical nature of the multi-dimensional Gaussian function, specification (iii) is not met and unwanted “valleys” are formed in the interpolation curve.

Figure 9. Selected F100 flight points for Example 3.3.

Figure 10. Gaussian neural network output for Example 3.3.
For comparison, the design procedure suggested by Moody [2,3] is used. There are 12 neurons used with centers as specified above. The exponent $\alpha$ is changed to 1, and the widths are chosen per (22): $s_{k1} = 1/T^2_1 = 16$ and $s_{k2} = 1/T^2_2 = 0.01$ for $1 \leq k \leq 12$. Note that two widths are used instead of one as suggested by Moody. Solving for $w$ in (9), the resulting interpolation curve is shown in Figure 11 with the same corner coordinates as the one in Figure 10. After examining the actual values for the curve, specification (i) is met. Specification (ii), however, cannot be satisfied for large $\varepsilon_j$, and in comparison to the curve in Figure 10, specification (iii) is better satisfied by the curve of Figure 11.

Figure 11. Moody's neural network output for Example 3.3.

4. CONCLUDING REMARKS

A particular neural network and a systematic design methodology are introduced so that prior information about the system's behavior can be directly and easily incorporated into the control design. Four possible uses for the proposed neural network architecture are dynamical system (plant and controller) modeling, fault detection and identification, information extraction, and control law scheduling, which was the one chosen to illustrate the design methodology. The method performs well for a designed scheduler with one-dimensional equidistant operating points, but not as well when the operating points are not equidistant. For designed schedulers with multi-dimensional operating points, the method has some drawbacks: a potentially large number of hidden layer neurons and the elliptical shape of the multi-dimensional Gaussian function contributing to unwanted “valleys” in the interpolation curve. Currently, methods to alleviate these problems are being investigated.

The results of this paper are also reported in [6], where the design procedure is explained in more detail and extended examples are described, and in [7], which contains a briefer description. An alternative approach to the problem addressed here is presented in [12], where neural networks with sigmoid nonlinearities instead of Gaussian nonlinearities are used. For a general discussion of neural networks and control systems, the interested reader is referred to [6,13].
