Heteroskedasticity

Richard Williams, University of Notre Dame, https://www3.nd.edu/~rwilliam/
Last revised January 10, 2020

These notes draw heavily from Berry and Feldman, and, to a lesser extent, Allison, and Pindyck and Rubinfeld.]

**What heteroskedasticity is.** Recall that OLS makes the assumption that

$V(\varepsilon_j) = \sigma^2$ for all j. That is, the variance of the error term is constant. (Homoskedasticity). If the error terms do not have constant variance, they are said to be heteroskedastic. [Tidbit from Wikipedia: The term means "differing variance" and comes from the Greek "hetero" ('different') and "skedasis" ('dispersion').]

**When heteroskedasticity might occur.**

- Errors may increase as the value of an IV increases. For example, consider a model in which annual family income is the IV and annual family expenditures on vacations is the DV. Families with low incomes will spend relatively little on vacations, and the variations in expenditures across such families will be small. But for families with large incomes, the amount of discretionary income will be higher. The mean amount spent on vacations will be higher, and there will also be greater variability among such families, resulting in heteroskedasticity.

  Note that, in this example, a high family income is a *necessary* but *not sufficient* condition for large vacation expenditures. *Any time a high value for an IV is a necessary but not sufficient condition for an observation to have a high value on a DV, heteroskedasticity is likely.*

  Similar examples: Error terms associated with very large firms might have larger variances than error terms associated with smaller firms. Sales of larger firms might be more volatile than sales of smaller firms.
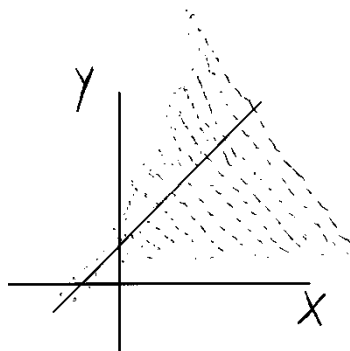

- Errors may also increase as the values of an IV become more extreme in either direction, e.g. with attitudes that range from extremely negative to extremely positive. This will produce something that looks like an hourglass shape:

- Measurement error can cause heteroskedasticity. Some respondents might provide more accurate responses than others. (Note that this problem arises from the violation of another assumption, that variables are measured without error.)

- Heteroskedasticity can also occur if there are subpopulation differences or other interaction effects (e.g. the effect of income on expenditures differs for whites and blacks). (Again, the problem arises from violation of the assumption that no such differences exist or have already been incorporated into the model.) For example, in the following diagram suppose that Z stands for three different populations. At low values of X, the regression lines for each population are very close to each other. As X gets bigger, the regression lines get further and further apart. This means that the residual values will also get further and further apart.
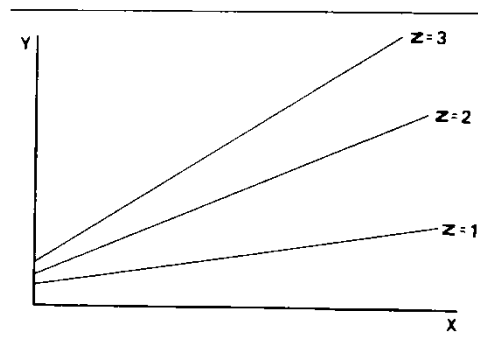

- Other model misspecifications can produce heteroskedasticity. For example, it may be that instead of using Y, you should be using the log of Y. Instead of using X, maybe you should be using X^2, or both X and X^2. Important variables may be omitted from the model. If the model were correctly specified, you might find that the patterns of heteroskedasticity disappeared.

Consequences of heteroskedasticity. Note that heteroskedasticity is often a by-product of other violations of assumptions. These violations have their own consequences which we will deal with elsewhere. For now, we'll assume that other assumptions except heteroskedasticity have been met. Then,

- Heteroskedasticity does *not* result in biased parameter estimates.

- However, OLS estimates are no longer BLUE. That is, among all the unbiased estimators, OLS does not provide the estimate with the smallest variance. Depending on the nature of the heteroskedasticity, significance tests can be too high or too low. As Allison puts it: "The reason OLS is not optimal when heteroskedasticity is present is that it gives equal weight to all observations when, in fact, observations with larger disturbance variance contain less information than observations with smaller disturbance variance."

- In addition, the standard errors are biased when heteroskedasticity is present. This in turn leads to bias in test statistics and confidence intervals.

- Fortunately, unless heteroskedasticity is "marked," significance tests are virtually unaffected, and thus OLS estimation can be used without concern of serious distortion. But, severe heteroskedasticity can sometimes be a problem.

Warning: Heteroskedasticity can be very problematic with methods besides OLS. For example, in logistic regression heteroskedasticity can produce biased and misleading parameter estimates. I talk about such concerns in my categorical data analysis class.

Detecting Heteroskedasticity

Visual Inspection. Do a visual inspection of residuals plotted against fitted values; or, plot the IV suspected to be correlated with the variance of the error term. In Stata, after running a regression, you could use the `rvfplot` (residuals versus fitted values) or `rvpplot` command (residual versus predictor plot, e.g. plot the residuals versus one of the X variables included in the equation). In SPSS, plots could be specified as part of the Regression command.

✓ In a large sample, you'll ideally see an "envelope" of even width when residuals are plotted against the IV. In a small sample, residuals will be somewhat larger near the mean of the distribution than at the extremes. Thus, if it appears that residuals are roughly the same size for all values of X (or, with a small sample, slightly larger near the mean of X) it is generally safe to assume that heteroskedasticity is not severe enough to warrant concern.
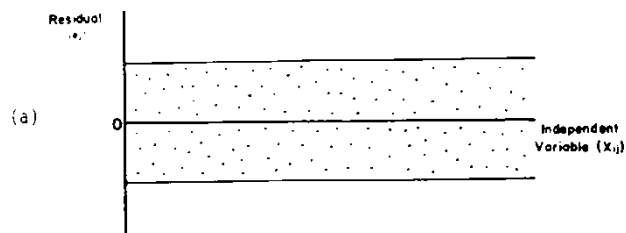

✓ If the plot of residuals shows some uneven envelope of residuals, so that the width of the envelope is considerably larger for some values of X than for others, a more formal test for heteroskedasticity should be conducted.

Breusch-Pagan / Cook-Weisberg Test for Heteroskedasticity. The Breusch-Pagan test is designed to detect any linear form of heteroskedasticity. You run a regression, and then give the `estat hettest` command (or, `hettest` alone will work). Using the reg01 data,

```
. use https://www3.nd.edu/~rwilliam/statafiles/reg01.dta, clear
. reg  income educ jobexp

      Source |       SS       df       MS              Number of obs =      20

       _cons |  -7.096855   3.626412    -1.96   0.067    -14.74791    .5542051
------------------------------------------------------------------------------

. estat hettest

Breusch-Pagan / Cook-Weisberg test for heteroskedasticity
        Ho: Constant variance
        Variables: fitted values of income

        chi2(1)      =       0.12
        Prob > chi2  =    0.7238
```

Breusch-Pagan / Cook-Weisberg tests the null hypothesis that the error variances are all equal versus the alternative that the error variances are a multiplicative function of one or more variables. For example, in the default form of the hettest command shown above, *the alternative hypothesis states that the error variances increase (or decrease) as the predicted values of Y increase, e.g. the bigger the predicted value of Y, the bigger the error variance is*. A large chi-square would indicate that heteroskedasticity was present. In this example, the chi-square value was small, indicating heteroskedasticity was probably not a problem (or at least that if it was a problem, it wasn't a multiplicative function of the predicted values).

Besides being relatively simple, hettest offers several additional ways of testing for heteroskedasticity; e.g. you could test for heteroskedasticity involving one variable in the model, several or all the variables, or even variables that are not in the current model. Type help hettest or see the Stata reference manual for details.

See Appendix A for details on how and why hettest works.

White's General Test for Heteroskedasticity. The default Breusch-Pagan test specified by hettest is a test for linear forms of heteroskedasticity, e.g. as $\hat{y}$ goes up, the error variances go up. *In this default form, the test does not work well for non-linear forms of heteroskedasticity, such as the hourglass shape we saw before (where error variances got larger as X got more extreme in either direction).* The default test also has problems when the errors are not normally distributed.

White's general test for heteroskedasticity (which is actually a special case of Breusch-Pagan) can be used for such cases. This can be estimated via the command `estat imtest, white` or just `imtest, white`. (Actually, the `white` option seems to matter rarely if ever in my experience; the Stata help says "White's test is usually very similar to the first term of the Cameron-Trivedi decomposition" normally reported by `imtest`.) You can also use Mark Schaffer's `ivhettest` (which offers several additional capabilities) or Baum & Cox's `whitetst`, both available from SSC. As the help for `whitetst` states,

> `whitetst` computes the White (1980) general test for heteroskedasticity in the error distribution by regressing the squared residuals on all distinct regressors, cross-products, and squares of regressors. The test statistic, a Lagrange multiplier measure, is distributed Chi-squared(p) under the null hypothesis of homoskedasticity. See Greene (2000), pp. 507-511.

NOTE: Part of the reason the test is more general is because it adds a lot of terms to test for more types of heteroskedasticity. For example, adding the squares of regressors helps to detect nonlinearities such as the hourglass shape. In a large data set with many explanatory variables, this may make the test difficult to calculate. Also, the addition of all these terms may make the test less powerful in those situations when a simpler test like the default Breusch-Pagan would be appropriate, i.e. adding a bunch of extraneous terms may make the test less likely to produce a significant result than a less general test would.

Here is an example using `estat imtest, white`:

```
. use http://www.nd.edu/~rwilliam/statafiles/reg01.dta, clear
. quietly reg income educ jobexp
. estat imtest, white

White's test for Ho: homoskedasticity
        against Ha: unrestricted heteroskedasticity

        chi2(5)     =        8.98
        Prob > chi2 =      0.1100

Cameron & Trivedi's decomposition of IM-test

---------------------------------------------------
            Source |      chi2     df       p
-------------------+-------------------------------
 Heteroskedasticity |      8.98      5    0.1100
          Skewness |      2.39      2    0.3022
          Kurtosis |      0.98      1    0.3226
-------------------+-------------------------------
            Total |     12.35      8    0.1363
---------------------------------------------------
```

As noted before, White's general test is a special case of the Breusch-Pagan test, where the assumption of normally distributed errors has been relaxed (to do this, use the `iid` option of `hettest`) and an auxiliary variable list (i.e. the Xs, the Xs squared and the cross-product/interaction terms) is specified:

```
. quietly reg  income educ jobexp
. estat hettest educ jobexp c.educ#c.educ c.jobexp#c.jobexp c.educ#c.jobexp, iid

Breusch-Pagan / Cook-Weisberg test for heteroskedasticity
         Ho: Constant variance
         Variables: educ jobexp c.educ#c.educ c.jobexp#c.jobexp c.educ#c.jobexp

         chi2(5)      =      8.98
         Prob > chi2  =    0.1100
```

See Appendix A for details on how and why `imtest` works.

Other Tests. There are lots of other tests for heteroskedasticity. They make different assumptions about the form of heteroskedasticity, whether or not error terms are normally distributed, etc. The readings go over some of these and if you give the command **findit heteroskedasticity** from within Stata you'll come up with more options.

Appendix B discusses the Goldfeldt-Quant test, which is somewhat antiquated, but which you may occasionally come across in your reading.

Dealing with heteroskedasticity

1.   Respecify the Model/Transform the Variables. As noted before, sometimes heteroskedasticity results from improper model specification. There may be subgroup differences. Effects of variables may not be linear. Perhaps some important variables have been left out of the model. *If these are problems deal with them first!!!* Don't just launch into other techniques, such as WLS, because they don't get to the heart of the problem.

Incidentally, Allison says (p. 128) "My own experience with heteroskedasticity is that is has to be pretty severe before it leads to serious bias in the standard errors. Although it is certainly worth checking, I wouldn't get overly anxious about it."

Warning: In general, I agree, with the qualifier that heteroskedasticity that results from model mis-specification is something to be concerned about. Indeed, I would say in such cases the problem isn't really heteroskedasticity, it is model mis-specification; fix that problem and the heteroskedasticity may go away. HOWEVER, by checking for heteroskedasticity, you may be able to identify model specification problems. So, *I would probably be a little more anxious about heteroskedasticity than Allison implies.*

2.   Use Robust Standard Errors. Stata includes options with most routines for estimating *robust standard errors* (you'll also hear these referred to as Huber/White estimators or sandwich estimators of variance)*.* As noted above, heteroskedasticity causes standard errors to be biased. OLS assumes that errors are both independent and identically distributed; robust standard errors

relax either or both of those assumptions. Hence, when heteroskedasticity is present, robust standard errors tend to be more trustworthy.

With regards to the related problem of error terms not being independent: Survey data are often collected using clustering, e.g. a sample will be drawn of areas and individuals within those areas will then be selected for inclusion in the sample. Also, some groups will be deliberately oversampled, e.g. your sampling scheme might be set up to include a disproportionately large number of minorities, in order to ensure that you have enough minorities to do subsample analyses of them. Such strategies can lead to violations of the assumption that the error terms are independent of each other (since people sampled in clusters tend to be more similar than people sampled totally at random). There is a good discussion of this in "Sampling Weights and Regression Analysis" by Winship and Radbill, Sociological Methods and Research, V. 23, # 2, Nov 1994 pp. 230-257.

Another example (given by Hamilton in *Statistics with Stata, Updated for Stata 9*, pp. 258-259: 51 college students were asked to rate the attractiveness of photographs of unknown men and women. The procedure was reported 4 times, producing 204 sets of records. Hamilton says "It seems reasonable to assume that disturbances (unmeasured influences on the ratings) were correlated across the repetitions by each individual. Viewing each participant's four rating sessions as a cluster should yield more realistic standard errors." In this case you add the `cluster(id)` option to the regression command, where id is the id number of the subject.

As Allison points out, the use of robust standard errors does *not* change coefficient estimates, but (because the standard errors are changed) the test statistics will give you reasonably accurate p values. The use of Weighted Least Squares (described next) will also correct the problem of bias in the standard errors, and will also give you more efficient estimates (i.e. WLS will give you estimates that have the smallest possible standard errors). But, WLS requires more assumptions and is more difficult to implement, so robust standard errors seem to be a more common and popular method for dealing with issues of heteroskedasticity.

With Stata, robust standard errors can usually be computed via the addition of two parameters, `robust` and `cluster`. The `robust` option relaxes the assumption that the errors are identically distributed, while `cluster` relaxes the assumption that the error terms are independent of each other. For example, rerunning the above regression with the `robust` option, we get

```
. reg  income educ jobexp, robust
```

```
Regression with robust standard errors             Number of obs =      20
                                                   F(  2,    17) =   48.15
                                                   Prob > F      = 0.0000
                                                   R-squared     = 0.8450
                                                   Root MSE      = 4.0743

------------------------------------------------------------------------------
             |               Robust
      income |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
        educ |   1.933393   .2006214     9.64   0.000     1.510119    2.356667
      jobexp |    .6493654   .1701214     3.82   0.001     .2904407    1.00829
       _cons |  -7.096855   3.365609    -2.11   0.050    -14.19767    .0039603
------------------------------------------------------------------------------
```

Note: You can also give the command

```
. reg income educ jobexp, vce(robust)
```

which is actually the preferred syntax for newer versions of Stata.

Comparing the results with the earlier regression, you note that none of the coefficient estimates changed, but the standard errors and hence the t values are a little different. Had there been more heteroskedasticity in these data, we would have probably seen bigger changes.

In some cases, Stata will use robust standard errors whether you explicitly ask for them or not. For example, if you have used clustering when collecting your data (and you tell Stata this via use of the `cluster` parameter) the error terms will not be independent. Hence, if you ever wonder why you are getting robust standard errors when you did not ask for them, it is probably because robust standard errors are more appropriate for what you are doing. (Indeed, with more complicated analyses, Stata will often surprise you by doing things you don't expect; if you can figure out why, you will learn a lot about advanced statistics!)

> Caution: Do not confuse robust standard errors with robust regression. Despite their similar names, they deal with different problems:
>
> *Robust standard errors* address the problem of errors that are not independent and identically distributed. The use of robust standard errors will not change the coefficient estimates provided by OLS, but they will change the standard errors and significance tests.
>
> *Robust regression*, on the other hand, deals with the problem of outliers in a regression. Robust regression uses a weighting scheme that causes outliers to have less impact on the estimates of regression coefficients. Hence, robust regression generally will produce different coefficient estimates than OLS does.

3.   Use Weighted Least Squares. A more difficult option (but superior when you can make it work right) is the use of weighted least squares.

> Weighted Least Squares is a more advanced method that I don't see sociologists using that often. It is therefore covered in the optional but recommended Appendix C.

4. Summary of recommendations for dealing with heteroskedasticity. In most instances, I would recommend option 1 (respecify the model or transform the variables) or option 2 (robust standard errors). Most of the examples I have seen using Stata take those approaches. However, in special cases, option 3 (WLS) can be the best. What makes WLS hard, though, is knowing what weights to use. The weights either have to be known for some reason or you have to have some sort of plausible theory about what the weights should be like, e.g. error terms go up as X goes up.

Appendix A: Heteroskedasticity Tests Explained [Optional]

This appendix elaborates on how and why some of the heteroskedasticity tests work.

hettest. Here (roughly) is how `hettest` works.

- First, you run a regression.

- Then, `hettest` uses the `predict` command to compute the predicted values ($\hat{y}$) and the residuals (e).

- The residuals are then squared and also rescaled so that their mean is 1. (This is accomplished by dividing each residual by SS Residual/ N, i.e. each squared residual is divided by the average of the squared residuals). The rescaling is necessary for computing the eventual test statistic.

- The squared residuals are then regressed on $\hat{y}$ and the test statistic is computed. The test statistic is the model (i.e. explained) sums of squares from this regression divided by two (take this part on faith!). If the null is true, i.e. there is no multiplicative heteroskedasticity, the test statistic has a chi-square distribution with 1 degree of freedom.

- If there is no heteroskedasticity, then the squared residuals should neither increase nor decrease in magnitude as $\hat{y}$ increases, and the test statistic should be insignificant.

- Conversely, if the error variances are a multiplicative function of one or more variables (e.g. as X increases, the residuals fall farther and farther from the regression line) then the test statistic will be significant.

Here is how you could interactively do the same thing that `hettest` is doing.

```
. use https://www3.nd.edu/~rwilliam/statafiles/reg01.dta, clear
. quietly reg  income educ jobexp

. * compute yhat
. predict yhat if e(sample)
(option xb assumed; fitted values)

. * Compute the residual
. predict e if e(sample), resid

. * Square the residual, and rescale it so that the squared values
. * have a mean of 1. This is needed for the eventual test statistic.
. gen esquare = e^2 / (e(rss)/e(N))
```

```
. * Regress squared residuals on yhat
. reg esquare yhat

      Source |       SS       df       MS              Number of obs =      20

```

Comparing this with our earlier results,

```
. quietly reg  income educ jobexp
. estat hettest

Breusch-Pagan / Cook-Weisberg test for heteroskedasticity
        Ho: Constant variance
        Variables: fitted values of income

        chi2(1)      =       0.12
        Prob > chi2  =     0.7238
```

---

imtest: Here (roughly) is how `imtest` works.

- First, you run a regression.

- Then, `imtest` uses the `predict` command to compute the residuals (e).

- The residuals are then squared. (You don't need to rescale like you did before.)

- `imtest` creates new variables that are equal to the X-squared terms and the cross-products of the Xs with each other. So, for example, if X1 is the only variable, `imtest` computes $X1^2$. If you had X1 and X2, `imtest` would compute $X1^2$, $X2^2$, and X1*X2. If you had three Xs, `imtest` would compute $X1^2$, $X2^2$, $X3^2$, X1*X2, X1*X3, and X2*X3.

- The squared residuals are then regressed on the original Xs, the squared Xs, and the cross-product terms. The test statistic $= N * R^2$. If the null is true, i.e. there is no heteroskedasticity, the test statistic has a chi-square distribution with $K*(K+3)/2$ degrees of freedom. [NOTE: with 0/1 dichotomies, the squared terms are the same as the non-squared terms, which will cause some terms to drop out, reducing the d.f.]

- If there is no heteroskedasticity, then the test statistic should be insignificant.

- Conversely, if there is heteroskedasticity, then the test statistic will be significant.

- `imtest` also produces some additional tests for skewness and kurtosis that I won't discuss here.

Here is how you could interactively do the same thing that `imtest` is doing.

```
. use https://www3.nd.edu/~rwilliam/statafiles/reg01.dta, clear

Appendix B: Goldfeldt-Quant (GQ) test [Optional]

[NOTE: This section is primarily included in case you come across this test in your readings. The tests we discuss above are now considered superior. Skim through this on your own.] The GQ test can be used when it is believed that the variance of the error term increases consistently or decreases consistently as X increases. The procedure is as follows:

- ✓ Order the data by the magnitude of the IV X which is thought to be related to the error variance.

- ✓ Omit the middle d observations. Typically, d might equal 20% of the sample size. This technically isn't necessary, but experience shows that this tends to improve the power of the test (i.e. makes it more likely you will reject the null hypothesis when it is false).

- ✓ Fit two separate regressions—one for the low values of X and one for the high. Each will involve (N - d)/2 cases, and [(N - d)/2 - 2] degrees of freedom.

- ✓ Calculate the residual sum of squares for each equation: SSE$_{low}$ for the low X's, and SSE$_{high}$ for the high X's.

- ✓ If you think the error variance is an *increasing* function of X, compute the following statistic:

$$F_{(N-d-4)/2,(N-d-4)/2} = \frac{SSE_{high}}{SSE_{low}}$$

If you think the error variance is a decreasing function of X, then reverse the numerator and denominator. This statistic assumes that the error process is normally distributed and there is no serial correlation. The F statistic should approximately equal 1 if the errors are homoskedastic. If the F value is greater than the critical value, we reject the null hypothesis of homoskedasticity.

- ✓ Note that this is a test of

$H_{0:}$ $\sigma_1^2 = \sigma_2^2 = \sigma_3^2... = \sigma_N^2$

H_A: $\sigma_1^2 = CX_i^2$ (Where C is some constant)

- ✓ You can easily modify the procedure when you have more than one IV in the model. Again, you order by *one* of the X variables (the one you think may be causing the problem). The other steps are the same, except that the F statistic is

$$F_{(N-d-2K-2)/2,(N-d-2K-2)/2} = \frac{SSE_{high}}{SSE_{low}}$$

(Note that in the bivariate regression case, K = 1, hence the first F test is just a special case of this one).

- ✓ To do this in Stata, you would do something like the following: Using the income, education, jobexp example I've used before, I dropped the middle 8 cases and produced the following.:

```

In this example, N = 20, d = 8, K = 2, SSE$_{high}$ = 45.54, SSE$_{Low}$ = 113.01. If there is heteroskedasticity, it is greater at lower values of education, ergo

$$GQ = F_{(N-d-2K-2)/2,(N-d-2K-2)/2} = \frac{SSE_{high}}{SSE_{low}} = F_{(20-8-2*2-2)/2,(20-8-2*2-2)/2} = F_{3,3} = \frac{113.01}{45.54} = 2.48$$

This is not significant at the .05 level.

- ✓ GQ is not helpful if you think there is heteroskedasticity, but it isn't monotonic, i.e. you think extreme values of X at either end produce larger error variances (like the hourglass shape we saw before).

- ✓ GQ has been found to be reasonably powerful when we are able to correctly identify the variable to use in the sample separation. This does limit its generality, however; sometimes heteroskedasticity might be a function of several variables. The other tests we discuss are more flexible and also simpler.

A more difficult option for dealing with heteroskedasticity (but superior when you can make it work right) is the use of weighted least squares. Generalized Least Squares [GLS] is a technique that will always yield estimators that are BLUE when either heteroskedasticity or serial correlation are present. OLS selects coefficients that minimize the sum of squared regression residuals, i.e.

$$\Sigma(Y_j - \hat{Y}_j)^2$$

GLS minimizes a *weighted* sum of squared residuals. In the case of heteroskedasticity, observations expected to have error terms with large variances are given a smaller weight than observations thought to have error terms with small variances. Specifically, coefficients are selected which minimize

$$\sum_{j=1}^{N} \frac{(Y_j - \hat{Y}_j)^2}{VAR(\varepsilon_j)}$$

OLS is a special case of GLS, when the variance of all residuals is the same for all cases. The smaller the error variance, the more heavily the case is weighted. Intuitively, this makes sense: the observations with the smallest error variances should give the best information about the position of the true regression line.

GLS estimation can be a bit complicated. However, under certain conditions, estimators equivalent to those generated by GLS can be obtained using a Weighted Least Squares (WLS) procedure utilizing OLS regression on a transformed version of the original regression model.

WLS CASE I. In WLS Case I the error variances are somehow miraculously known. Since that rarely if ever happens I won't bother discussing it.

WLS CASE II. A far more common case is when we think the error variances vary directly with an IV. For example, suppose we think there is heteroskedasticity in which the standard deviation of the error term is linearly related to X1, i.e.

$$\sigma_i = CX_{1i}$$

In other words, the larger X is, the more error variability there will be.

Using Stata for WLS Case II. The `aweights` parameter (analytical weights) in Stata provides one means for doing WLS. Take the X which you think is causing the heteroskedasticity, and proceed as follows:

```
. gen inveduc = (1/educ)^2

. reg income  educ jobexp [aw = inveduc]
(sum of wgt is   4.4265e-01)

      Source |       SS       df       MS              Number of obs =      20
-------------+------------------------------           F(  2,    17) =   86.20
       Model | 1532.21449      2  766.107244           Prob > F      =  0.0000
    Residual | 151.090319     17  8.88766581           R-squared     =  0.9102
-------------+------------------------------           Adj R-squared =  0.8997
       Total | 1683.30481     19  88.5949898           Root MSE      =  2.9812

------------------------------------------------------------------------------
      income |      Coef.   Std. Err.       t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
        educ |   1.795724   .1555495     11.54   0.000     1.467544    2.123905

------------------------------------------------------------------------------
```

Note that both the coefficients and the standard errors are different from before. If we were confident that we were using the correct weights, this would be a superior solution to anything we have done before. If, however, the weights are wrong, we may have just made things worse! I actually prefer SPSS for WLS (at least for Case II), because I think it provides a better test of what weighting scheme is best.
