We have made a naked diatomic diion of bismuth with a short Bi—Bi bond of 2.8377(7) Å that suggests possible multiple bonding. While diatomic molecules with multiple bonds are known among the lighter elements and are abundant in nature (O₂ and N₂ account for 99% of the atmosphere, C₂²⁻ in CaC₂), they are rare or nonexistent among the heavier main-group elements (only S₂, Se₂, and P₂ at high temperatures). Substituted diatomic species with multiple homoatomic bonds, on the other hand, have become quite common. Numerous examples of RP=PR, R₂As=AsR₂, R₂S=SiR₂, and R₂Ge=GeR₂ are known.¹ In addition to these, a few examples of the heaviest pnicogenos, Sb and Bi,² and group 14 congeners, Sn and Pb,³ have been made more recently although the multiplicity of the bonds in the latter two is questionable. A triply bonded gallium molecule was also reported,¹ but the multiplicity of its bond has been also disputed ever since.² An important feature common for all of these substituted species is the extremely bulky organic substituents that stabilize the species but at the same time makes them inaccessible for reactions. The multiple bonds are the result of the abnormally low coordination that is sterically forced by the organic groups. There is also a number of substituted diatomic species with single bonds.¹,²,⁶ Simply bonded naked molecules are also known but all in insoluble neat solids. Examples are CaP, CaAs, Ca₁₅Sb₁₀, and Ca₁₁Bi₁₀ with P₄⁺, As₄⁺, Sb₄⁺, and Bi₄⁺, respectively, and Ca₅Si₃, Ca₅Ge₃, Ba₅Sn₃, and Ba₅Pb₃ which contain Si₂⁻, Ge₂⁻, Sn₂⁻, and Pb₂⁻, respectively.⁸ All of these are isoelectronic with the well-known soluble oxide O₂⁻, S₂⁻, and the neutral diatomic molecules of the halogens. This collection, until now, lacked a naked diatomic molecule with a double bond. We report here the synthesis and structure of the soluble (K-crypt)₂ Bi₂ (1) which contains Bi²⁺ with a very short bond distance.¹⁰

(10) Bobev, S.; Sevov, S. C., unpublished results. The precursor was initially synthesized by a reaction designed to explore for clusters of [InBi₃]⁻ that are isoelectronic with the known Pb₁₆⁻ found in K₉Pb₂₆ (Queneau, V.; Sevov, S. C.; Inorg. Chem. 1998, 37, 1358). Thus, a mixture of the elements with stoichiometry K₁₂InBi₁₆ was heated in a welded niobium container sealed in evacuated quartz ampule at 600 °C for a week. Later K₄InBi₄ was made starting from the correct stoichiometry.

(11) Redistilled ethylenediamine packaged under nitrogen (99.5%, Aldrich) and crypt (Kryptofix 222, 98%, Acros) were used as received, and the toluene (99.5%, Fisher) was dried and kept over sodium. All operations of the dissolution and crystalization were performed in a helium-filled glovebox.

(14) The number of bonding electrons in the clusters (SnBi₃)⁻ and (PbBi₃)⁻ is 9 × 2 + 3 = 21, and therefore the clusters are paramagnetic, while this number for (InBi₃)⁻ is 4 × 1 + 5 × 3 = 18 and indicates diamagnetic clusters of SnBi₃⁻ and PbBi₃⁻ on the other hand, have 2 × 2 + 2 × 3 = 12 bonding electrons, the same as for (InBi₃)⁻, i.e., 1 × 1 + 3 × 3 = 2 × 3.

(15) A six of a sphere of X-ray diffraction data (2θmax = 50°) was collected at room temperature on CAD4 with Mo Kα radiation from a single crystal of (K-crypt)₂Bi₂ (plate, red-brown, 0.60 × 0.48 × 0.05 mm). Crystal data: triclinic, R₁, Z = 2, = 3, a = 12.229 Å, c = 28.927 Å, V = 3740.9(5) Å³, μ = 7.68 cm⁻¹, dcalc = 1.66 g·cm⁻³, R1/wR2 = 2.836%/8.2% for the observed 1298 reflections (İ = 2 0) and R1/wR2 = 3.417%/12.0% for all 1437 reflections and 134 variables. All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were located from difference Fourier maps and were fully refined with isotropic thermal parameters. The structure solution and refinement (on F²) were handled with the SHELXTL-V5.1 package. The data were corrected for absorption using a lambda-g model with the aid of seven g-scans at different θ-angles (min/max transmission = 0.1699/0.7360). Qualitative microprobe elemental analysis (energy-dispersive X-ray analysis for elements heavier than oxygen) performed on the same crystal showed Bi and K only.

due to the simplicity of the molecules it contains, Bi$_2^{2-}$. The naked dianions (Figure 1) are oriented along the 3-fold axis. Each molecule is surrounded by eight [K-cript]$_2$ cations, two are along the molecular axis (shown in Figure 1) and the other six are around the molecule in two sets of three on both sides of the equatorial plane. The closest neighbors to the bismuth atoms are aliphatic hydrogen atoms at distances of 3.47 Å and longer. The corresponding carbon atoms are at distances larger than 3.9 Å. These distances are longer than the sums of the corresponding van der Waals radii ($r_{vdw} = 1.20$ and 1.70 Å for H and C, respectively, estimated $r_{vdw} = 2.02$ Å for Bi), and therefore the molecule is indeed isolated and nonbonded.

The Bi–Bi distance is 2.8377(7) Å. It compares very well with observed double-bond distances between bismuth atoms in substituted diatomic species, 2.8208(8) Å in [2,4,6-(Me$_3$Si)$_2$CH]$_2$Bi$_2$ and 2.833(1) Å in [2,4,6-Me$_6$C$_6$H$_3$]$_2$Bi$_2$.24 The distance in Bi$_2^{2-}$ is slightly longer, most likely due to the electrostatic repulsion of the negative charges. This is very similar to C$_2^{2-}$ in CaC$_2$ with a C–C distance of 1.19 Å,16 and the C–C distance of 1.18 Å in the corresponding H-substituted acetylene.160 It has already been shown that these distances correspond to a double bond for bismuth,6 a,b,s,17 The Bi–Bi distance of 2.8377 Å in I corresponds to a Pauling bond order of 2.01.18 For comparison, the Bi–Bi distances in dimers with single bonds are 2.990(2) and 3.035(3) Å in the substituted Pb$_2$Bi$_2$ and (Me$_3$Si)$_2$Bi$_2$, respectively,6 and 3.15 Å in the naked Bi$_2^{2-}$ anions found in Ca$_3$Bi$_4$.19

There are different possibilities for the electronic structure of the Bi$_2^{2-}$ species. The molecule is a 12-electron system, isoelectronic with known species such as B$_2$H$_6$, C$_2$H$_2$, N$_2$H$_2$, and O$_2$. Although isoelectronic the latter four show different bonding modes, i.e., diborane is double-bridged, ethylene and diazene are with one σ and one π bonds, while oxygen is with a double bond but with one σ- and two π-type orbitals where two unpaired electrons occupy the two π* MOs, making it paramagnetic. Since there are no substituents on Bi$_2^{2-}$ it is likely to be O$_2$-like. Ab initio calculations were performed on the species (with electron correlation and relativistic effective-core potentials, B3LYP functional with (4s4p1d)/(2s2p1d)20,21) The optimized distances from these calculations, 2.954 Å for the triplet and 2.958 Å for the singlet states, are in substantial disagreement with the experimental 2.8377 Å. This is most likely due to the assumption that the species are isolated in gas phase with no counterbalancing.

Figure 1. An ORTEP drawing (50% probability level for the thermal ellipsoids) of Bi$_2^{2-}$ and the two neighboring K-cript cations along the bond direction (see text). The carbon and hydrogen atoms are shown as crossed ellipsoids and open circles, respectively. The bismuth, potassium, nitrogen, and oxygen atoms are drawn as ellipsoids with shaded segments.

(18) Pauling, L. Nature of the Chemical Bond, 3rd ed.; Cornell University Press: New York, 1960; p 239: The relationship of bond order to length is given by $d = d_i - \log(n)$ where $n$ is the bond order, $d_i$ and $d$ are the lengths of bonds with bond order 1 and $n$, respectively, and $C \approx 0.6$. The length of a single Bi–Bi bond according to Pauling is 3.02 Å, and therefore $n = 2.01$ for a distance of 2.8377 Å.

cations. The calculations also suggested triplet ground state. To test the latter we measured the magnetization of the solid compound and the EPR of the solid and solution of the redissolved compound at different temperatures.22 These measurements showed diamagnetic behavior and therefore a singlet ground state for the molecule. There are a few possible reasons for the “failure” of the calculations. One is that the bond distance was not optimized accurately to begin with. Second, it has been pointed out that “theoretical investigations of anions is traditionally among the most demanding fields in quantum-mechanical ab initio calculations” due to: (1) the much larger correlation energy of anions compared to neutral molecules, and (2) the much more diffuse electron density of anions.23 Third, bismuth is very heavy and its relativistic effects are difficult to handle in calculations. As a consequence, “much more sophisticated treatments of the correlation energy combined with one-particle basis sets augmented by diffuse and high angular momentum functions are required for an appropriate description of the extra electrons in anions.”23 or in other words, the calculations should be done at much higher level in order to assay the real electronic state of the Bi$_2^{2-}$ species.

It is important to note also that our attempts to make 1 from precursors containing only K and Bi (nominal compositions “K$_2$Bi$_2$”, treated similarly as the synthesis of K$_5$In$_2$Bi$_4$) were unsuccessful. The product contains only the known (K-cript))$_2$Bi$_3$ with squares of Bi$_2^{2-}$.24 The latter can be thought as made of two Bi$_2^{2-}$ by oxidative ring formation, 2Bi$_2^{2-}$ = 2e$^- \rightarrow$ Bi$_2^{2-}$. The reason for the different outcomes from the different precursors is not clear, although it can be speculated that the structure of K$_5$In$_2$Bi$_4$ and the formal charges of the bismuth atoms in it are important for the formation of Bi$_2^{2-}$. The precursor K$_5$In$_2$Bi$_4$ contains chains of edge-sharing tetrahedra of bismuth centered by indium, and the chains are separated by the potassium cations. There are one-, two-, and three-bonded bismuth atoms with formal charges of 2$^-$, 1$^-$, and 0, respectively. The “K$_2$Bi$_2$” precursor, on the other hand, contains elemental potassium and the compound KBi$_2$. The latter is isostructural with the so-called Laves phase MgCu$_2$, a structure typical for alloys with a network of heavily interconnected Bi-atoms with uniform formal charges of 0.5$. This means that the atoms are not reduced enough for the formation of Bi$_2^{2-}$ where the charge per atom is 1$^-$. The availability of low-coordinated bismuth atoms with very negative charges in K$_5$In$_2$Bi$_4$ clearly makes the difference. Furthermore, the other two phases that cocrystallize with 1 are with less reduced bismuth, formally Bi$_2^{2+}$ in 2 and Bi$^{3+}$ in 3. Also, they “extract” the indium atoms from the chains and provide the highly charged bismuth atoms for the formation of the dimers. Experiments to use alkali-metal rich precursors such as K$_3$Bi containing isolated Bi$^{2+}$ species are in progress, and may prove more appropriate and rational for the synthesis of Bi$_2^{2-}$.

(22) The magnetization of more than 30 mg of 1 sealed in a quartz tube was measured at a field of 3 T over the range 4–290 K on a Quantum Design MPMS SQUID magnetometer. It showed diamagnetic, temperature-independent behavior. For the EPR measurements a few large crystals of 1 were ground into fine powder that was then sealed in a quartz tube, and later the same powder was redissolved in ethylenediamine, placed in a tube, and measured again. Spectra were recorded at 8, 80, 120, and 295 K. There was no signal from either the solid or the solution.
